To Diane, Sonya, and Joshua, with whom I can now get reacquainted, and to my parents, who made me.

EQUIPMENT NEEDED

To use the programs in this book, you will need the following equipment:

- An Apple II Plus, IIe, or IIc (Chapter 12 requires either a IIc or an extended-memory IIe)
- A disk drive
- A monitor (color for Chapter 11 and part of Chapter 12)
- A joystick or paddle
- An assembler (see the What You Will Need section)

What You Will Need

If you have an Apple II (II+, IIe, or IIc), and someplace to plug it in, you're practically all set. You will need a disc drive and a display screen, which can be either a black and white or color monitor or television set. Monitors give sharper pictures and are recommended, especially for double hi-res, but television sets are adequate. You should also have a joystick or paddle controls.

You will also need a good assembler. Assemblers are software packages that allow you to write and, more importantly, edit assembly language programs. Strictly speaking, you don't need an assembler to enter the programs in this book (you could use the Apple's resident Monitor or even BASIC), but the level of inconvenience would be unbearably high. Also, for you assembly language beginners out there, don't be lulled by those who may tell you that the Apple's Mini-Assembler or some other simple assembler is sufficient for your needs. The most important characteristic of full feature assemblers is their convenience, not their complexity. To eliminate long hours of needless work, and certainly if you're going to do any serious assembly language programming, a full feature assembler is a necessity. All programs in this book were assembled using the BIG MAC assembler (available from A.P.P.L.E., 290 S.W. 43rd St., Renton, WA 98055; call 1-800-426-3667 to order), but any full feature assembler can be used as they all employ the same basic command set. Among others I can recommend are Orca/M (Hayden Software), Merlin (Southwestern Data Systems), and DOS Tool Kit (Apple Computer, Inc.). These are available in computer stores and are also discounted by mail order firms-check the software ads in any computer magazine. If you don't want to invest in an assembler just now, contact your local Apple user's group—you may be able to borrow an assembler for temporary use.

There are usually some minor differences from assembler to assembler but these are almost always in extra features rather than in the basic system. Features of the BIG MAC assembler used in this book that may not be found in other assemblers are pointed out in the text along with the normal or standard instructions. If you're not going to use BIG MAC, examine your assembler's instruction manual. This, together with an examination of the generated machine code, will tell you what changes, if any, have to be made in the way the assembly code is written.

. I .

ntroduction

A art One of this book will lead you, step-by-step, through the construction of a single, arcade-type hi-res game written entirely in Apple II assembly language. Each chapter in Part One provides a building block leading to the final game with minimal digressions. Later chapters (Part Two) discuss aspects of hi-res animated graphics important to the subject but not directly related to the game, with suggestions about how to apply these techniques to the game itself or to your own programs.

The game we're going to construct is relatively simple but the program code is not. Hopefully, reading this book will reduce the level of difficulty to manageable proportions. It is written for beginners and experienced users alike and no prior knowledge of assembly language is required. It begins with a discussion of bits and bytes, binary and hexadecimal numbering systems, architecture of the Apple II hi-res screens, use of an assembler, and proceeds with a discussion of drawing and animating shapes, paddle and joystick controls, collision detection, scoring and sound, and finally the game itself. Other topics discussed in both Parts One and Two include animating multiple shapes, drawing over backgrounds, animation in color and in double hi-res color and black and white, advanced paddle and joystick routines, and integrating BASIC with assembly language programs.

Studying this book slowly and methodically will provide you with knowledge of the elements of hi-res game design for the Apple and you will be able to program your own hi-res animation routines in assembly language. However, it should be emphasized that the skills you will acquire have utility far beyond merely designing games. Let me give you a concrete example. I've recently completed an educational program for the Apple II that required moving rather large shapes around the screen and attempts to do this from BASIC using Apple shape tables (we'll discuss these in Chapter 1) were far from satisfactory. The jerky, flickering animation seemed designed to ensure nervous blinking. Using the simple principles described in this book, I was able to produce smooth, professional-looking animation that contributes greatly to the visual appeal of the program, which is one of its strong selling points. So even if game design is not your goal, hi-res animation using assembly language will provide you with an extremely useful tool for a myriad of applications, limited only by your imagination.

Finally, I strongly encourage you to play an active role in the learning process. Do not merely read the text; type in the programs. Try the advanced techniques described in Part Two to modify the game and, above all, develop your own programs. In this way you will learn not only the techniques of hi-res graphics and animation but also many fundamental principles of assembly language programming. Reading about assembly language instructions is one thing but using them in your own programs is another. In the words of an ancient Chinese philosopher,

> I bear, and I forget, I see, and I remember, I do, and I understand.

PART ONE

Fundamentals and the Game

Why Assembly Language for Hi-Res Animated Graphics?

An English teacher named Bea Knew the dictionary from A to Z, But upon buying an Apple She then had to grapple

With a brand new vocabulary.

Programming in assembly language is not the only way to produce hi-res animated graphics on the Apple II. Applesoft BASIC supports many graphics features that can be quite useful for displaying shapes or moving one or two relatively small shapes around the screen. In fact, it is often convenient to combine graphics from BASIC with assembly language graphic routines, and we will discuss how to do this in Chapter 16. But, as we'll soon see, there are problems associated with using BASIC for graphics programming.

Simple BASIC commands allow one to plot points or lines (and thus shapes) on the hi-res screen and to move them around by erasing and redrawing at a new position. For example, the following BASIC program plots a horizontal line and moves it down one line:

10 HGR: REM CLEARS AND DISPLAYS HI-RES SCREEN 20 HCOLOR=3: REM COLOR SET TO WHITE 30 HPLOT 20,20 TO 100,20: REM DRAWS HORIZONTAL LINE 40 HCOLOR=0: HPLOT 20,20 TO 100,20: REM ERASES LINE BY REDRAWING IN BLACK 50 HCOLOR=3: HPLOT 20,21 TO 100,21: REM REDRAWS LINE IN NEW POSITION

The line can be made to traverse the screen by continuing the program and changing plot coordinates. One can also draw vertical or diagonal lines and move them across the screen. By specifying different values for HCOLOR, the lines can be drawn in any of the four hi-res colors (blue, orange, violet, and green). This routine is fine for drawing and moving lines, but is far too cumbersome for complicated shapes and entirely inappropriate for rapid and smooth animation— BASIC is just too slow. Consider that even a simple shape may consist of 5 or 10 lines, and moving a shape across the entire hi-res screen involves over 200 drawerase cycles. Now imagine a routine to move several such shapes at the same time. Attempting to do this in BASIC, in the way described above, would result in an enormous, and enormously difficult to write, program. In addition, the animation would be extremely slow and jerky.

There is yet another method for programming hi-res graphics from BASIC and this involves using Apple shape tables. Details are contained in the Apple BASIC manual so I will touch on the subject only briefly. The instructions for drawing a shape (not the shape itself) are stored somewhere in memory in what are called, appropriately enough, shape tables. A single shape table can contain instructions for more than one shape. For example, to draw the first shape of a shape table, the location of the table is specified by POKEing the appropriate numbers into certain memory locations. Then the color is chosen by assigning a number to HCOLOR, and values for rotation (ROT) and scale (SCALE) are specified. The instruction DRAW 1 AT X,Y will draw the first shape of the table at the coordinates specified by X and Y. By changing the HCOLOR value, the shape can be drawn in different colors. Changing the values for ROT and SCALE allows one to rotate the shape and scale it up in size (although this latter feature is of limited usefulness because the scaling is not proportional). The shape can be erased by the instruction XDRAW 1 AT X,Y or by changing the color to black (HCOLOR = 0) and reDRAWing at X,Y. By crasing and redrawing at different nearby coordinates, the shape can be made to appear to move.

Using shape tables is a neat and convenient way to program hi-res graphics, but there are three problems associated with their use. First, although any of the hi-res colors can be selected, the shape can be only one color-multiple colors in a single shape is not possible. Second, constructing a shape table in the way described in the Apple BASIC manual is a horrendous task. The manual itself recommends using one of the many commercially available utility programs for this purpose—an example is the Apple Mechanic program from Beagle Bros. Such utilities work well (you draw the shape, point by point, and the program assembles it automatically into a shape table) but, as is often the case with someone else's program, you may not be able to get it to do what you want it to do. The Apple Mechanic, for example, limits the overall size of the shape and this may not be appropriate for your needs. Third, smooth and rapid animation with large shapes or with many shapes moving at the same time is not possible using shape tables. The draw, erase, redraw cycles are just too slow, and excessive flickering and jerky movement are the results. Again, as with HPLOTting, shape tables do not have their place (I use them in my own commercial programs), but they do not provide the versatility afforded by assembly language programming.

There are a few graphics utility programs on the market that purport to greatly simplify hi-res animation and they do. But they also, in my hands at least, suffer from many of the problems associated with shape tables and graphics from BASIC and thus, in my opinion, have limited usefulness. Again, using someone else's program almost assuredly will place limits on what you can do. For example, the programs I am familiar with limit the size of the shapes and the number of shapes you can display at any one time. Most have no provision for sound. They are also too slow—the more and larger the shapes, the slower and jerkier the animation. Some of these programs may satisfy your particular needs but don't buy one without return privileges.

The essence of good animation is speed. The illusion of continuous movement can be accomplished only by very rapid draw and erase cycles, especially for large shapes. This also applies in the case of the game we're going to construct, where one desires the illusion of simultaneous movement of multiple shapes. Assembly language provides this speed—in fact, as we'll soon see, assembly language speed is so great that time delays have to be placed in the game program to slow down the action to a reasonable pace.

In addition to speed, assembly language provides the ultimate in versatility. You want to draw and move a shape that takes up half the screen? OK, no problem. How about moving five shapes in different directions at the same time, with sound effects and all possible colors? Also no problem (actually, it is a problem but solvable with assembly language).

Finally, if you're like I am, you want to know and control what's going on. How is your computer drawing and moving all those shapes? Using someone else's program or using BASIC or shape tables tells you very little. Writing your own assembly language programs tells you a great deal.

Speed, versatility, understanding—only assembly language provides this combination of virtues.

Bits and **B**ytes, **S**ugar and **S**pice

There once was a fellow named Tex Whose computer kept him from sex. When offered a slumber By a cute little number

He said, "I really prefer binary and hex."

certain minimal knowledge of binary and hexadecimal numbering systems, the Apple memory map, details of the hi-res screens, and the use of an assembler is necessary before going on to a discussion of assembly language hi-res drawing and animation. Those who know this material can skip to Chapter 3. Those who don't will need to slog their way through this chapter. I'll try to make the slogging as painless as possible.

BINARY NUMBER SYSTEM

Computers operate essentially by using thousands of 2-position switches. Everything a computer does, taking in data (or text, which to a computer is just another form of data), manipulating it, and sending it out to a screen or printer or other device, is all controlled by these switches. A switch can either be on or off (more precisely, high voltage or low voltage). If we assign a 1 and a 0 to these alternate states, we then have a way of representing the status of these switches with numbers. To "talk" to a computer, to tell it what to do, we have to set its switches by talking its language. The only language a computer understands is the language of 0's and 1's, which comprises what is called a binary number system. Higher level computer languages, such as BASIC, use interpretive programs to convert text and decimal number instructions into a binary form. To use lower level languages, such as assembly language, and to understand hi-res graphics, some understanding of the binary system is required.

In any language, all possible words are represented by arranging the alphabet characters in different combinations. Computer "words" are numbers and the computer "alphabet" is 0 and 1. How can just two digits be used to represent more than two numbers? The universally used numbering system is, of course, the decimal system which uses ten digits, 0 to 9, to represent all possible numbers (this is undoubtedly related to the fact that we have ten fingers and toes; if we had only two, we would probably be balancing our checkbooks in binary). We have to realize that the decimal system is just as arbitrary as any other system using any other number of digits. Thus, to understand the binary system requires only an understanding of the principles of the decimal system.

The decimal system works by column assignments. There is no single digit to represent the number ten, so a 1 is placed in a second column, the tens column. Similarly, we represent one hundred by placing a 1 in the third or hundreds column. Each column represents some whole factor of 10.

	100's 10²		1's 10 ⁰	
4	3	2	7	= 4000 + 300 + 20 + 7 = 4327

In the binary system, we can count to one easily enough (zero, one) but there is no single digit to represent the number two so we place a 1 in a second column. Thus, binary 10 = decimal 2 and, it follows, binary 11 = decimal 3. What is decimal 4? Very good. It's binary 100. Thus, the binary system uses columns just like the decimal system except the columns are now factors of two.

8's 2 ³	4's 21	2's 2'	1's 2 ⁰	Decimal
0	0	0	0	0
0	0	0	1	1
0	0	1	0	2
0	0	1	1	3
0	1	0	0	4 5
0	1	0	1	
0	1	1	0	6
0	1	1	1	7
1	0	0	0	8
1	0	0	1	9
1	0	1	0	10
1	0	1	1	11
1	1	0	0	12
1	1	0	1	13
1	1	1	0	14
1	1	1	1	15

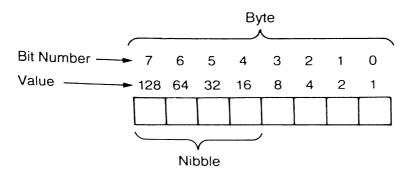

Columns can be extended to a 16's column, 32's column, etc. and so given enough columns, we can represent any number by stringing together 0s and 1s.

7

THE HEXADECIMAL NUMBERING SYSTEM

Writing numbers in binary is obviously a laborious task and is also prone to errors—try copying a string of a hundred 0's and 1's and see how far you get without making a mistake. To avoid these problems, assembly language uses yet another numbering system, the hexadecimal system. An interpreter program converts hexadecimal (or hex for short) numbers into the binary format so the computer can understand what's going on. It will be easier to understand the hexadecimal system if we first discuss some aspects of how the Apple handles numbers.

Each position of a binary number is called a bit. A group of 4 bits is called a nibble and a group of 8 bits is called a byte.

The Apple II is an 8-bit machine; that is, its microprocessor handles 8 bits (1 byte) of data at a time. It's convenient to represent a nibble by a single hex number; thus two hex numbers can represent a single byte. If we look at the table below, we see that a nibble can have values from 0 to 15. We have only ten digits (0-9) to work with, so numbers 10 to 15 are assigned letters A to F (hex numbers are preceded by a \$ sign to distinguish them from decimal numbers).

Decimal	Binary	Hex
0	0000	¢0
1	- • •	\$0
		\$1
2 3	0010	\$2
3	0011	\$3
4 5	0100	\$3 \$4 \$5
5	0101	φ ¢
6	0110	φ <u></u> Ο
7	<u> </u>	\$6
8	•••	\$7
	1000	\$8
9	1001	\$9
10	1010	
11		\$A
12	1011	\$В
	1100	\$C
13	1101	\$D
14	1110	
15		\$E
· •	1111	\$F

Now we've simplified things somewhat. It's obviously easier to write \$F than 1111.

Most of the time we'll be writing numbers as bytes and here the advantage of hex numbers becomes more apparent. To write a byte in hex, we simply assign a hex number to each nibble, e.g.,

Decimal	Binary	Hex
98	$\underbrace{\begin{array}{cccc} 0 & 1 & 1 & 0 \\ & & & & \\ & & & \\ & & & \\ & & & & \\ & & & & \\ & & & \\ & & & & \\ & & & & \\ & & & & \\ & & & & \\ & & & & \\ & $	\$62
198	$\underbrace{\begin{array}{ccccccccccccccccccccccccccccccccccc$	\$C6
255	$\underbrace{1 1 1 1}_{\$F} \underbrace{1 1 1 1 1}_{\$F}$	\$FF
1	$\underbrace{\begin{array}{ccccccccccccccccccccccccccccccccccc$	\$01

If you ever feel an irresistible urge to convert hex numbers into binary, you simply take each hex digit and write the corresponding binary nibble. Converting hex to decimal and vice versa is often useful (BASIC uses only decimal numbers). This can be done easily if you understand that the hex system also uses column assignments, just as binary and decimal, but here the columns are factors of 16 (hence the name hexa[6]decimal[10]) because there are 16 digits possible in each column.

16's 16'	1's 16 ⁰	Hex	Decimal
\$1	\$0	\$10	16
\$2	\$0	\$20	32
\$2	\$A	\$2A	42
\$6	\$2	\$62	98

THE APPLE II MEMORY MAP

The Apple 6502 microprocessor stores numbers in specific locations called memory addresses. Each memory address can hold only one byte. The maximum value of a byte is \$FF (11111111 or 255 decimal)—this explains why 255 is the maximum value you can use to POKE to a memory location in BASIC. When

these addresses are scanned, a byte is retrieved from each location and depending on the value, a given operation is performed. Memory addresses are accessed by a system that can handle two bytes of data at a time. Two bytes can be represented by four hex numbers, and so a memory address has the general form \$NNNN where N equals any hex number. Assemblers always access addresses using the hex format. We can convert memory addresses from hex to decimal (useful when using BASIC and assembly language in the same program) by column assignments; e.g.:

4096's 16 ³	256's 16²	16's 16'	1's 16º	Hex	Decimal
				<u>пе</u> д	
\$0	\$0	\$A	\$0	\$00A0	160
\$0	\$8	\$0	\$0	\$0800	2048
\$2	\$0	\$0	\$0	\$2000	8192
\$4	\$0	\$0	\$0	\$4000	16384
\$6	\$0	\$0	\$0	\$6000	24576
\$9	\$6	\$0	\$0	\$9600	38400
\$F	\$F	\$F	\$F	\$FFFF	65535

The highest memory address is \$FFFF; i.e., all 16 bits are 1. Thus the 6502 microprocessor can access only 65536 addresses (\$0000 is the first memory location)—from this comes the term 64K of memory. Apples with 128K of memory switch between two memory banks, each one containing 65536 addresses; Apples with less than 64K of memory have the capability of accessing 65536 addresses—it's just that they're not all there.

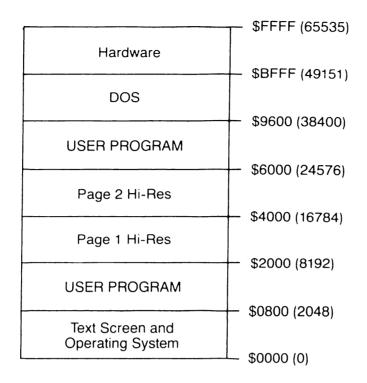

Memory addresses are conveniently divided into what are called pages, each page containing 256 bytes.

Address Bytes	Hex Address	Page Number
0-255	\$0000-\$00FF	0
256-511	\$0100-\$01FF	1
512-767	\$0200-\$02FF	2
etc.		

Thus, addresses in the range \$0000 to \$00FF are called zero page addresses. We'll meet up with these later on as they play an important role in some of the assembly language instructions used in our programs.

Memory addresses themselves are often stored at other memory addresses for use in a program. Because an address can store only one byte but is itself represented by two bytes (except for zero page addresses), we have a problem. The solution is to store an address in two locations, one byte in one and one byte in the other. This is done in a particular way. Memory address bytes are divided into two classes, the high order byte (left) and the low order byte (right). For example, \$20 is the high byte and \$00 the low byte of address \$2000. The bytes are stored in consecutive locations, low byte first. We'll learn more about this when we get to our programs in later chapters.

There are several general areas of memory that play a distinctive role in the operation of the Apple II. The following memory map describes and locates some of these functions.

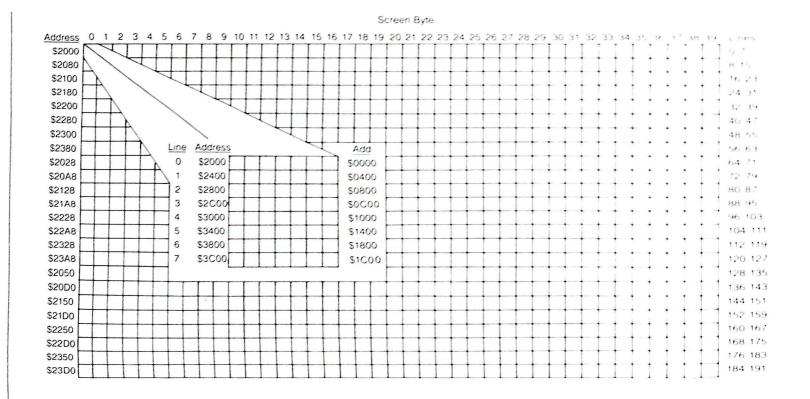

THE HI-RES SCREENS

There are two areas reserved for hi-res graphics, Pages 1 and 2 (these page numbers have nothing to do with the page numbers of memory addresses discussed above). Page 1 occupies an area from \$2000 to \$3FFF and Page 2 from \$4000 to \$5FFF. Either page can be used for any hi-res graphics program, the only difference being that Page 1 has the option of displaying full-page graphics or mixed text and graphics, the bottom four lines displaying the text. So if you want to display text and graphics, choose Page 1. For full page graphics, you can choose either page. The only other point to consider in choosing pages is whether you're going to use a BASIC program along with your assembly language program. BASIC requires a continuous stretch of memory, so the page choice determines the maximum length of your BASIC program. For example, if you choose Page 1, you can run BASIC from \$0800 to \$1FFF or load the BASIC program above Page 1 and run it from \$4000 to \$9600. This will be discussed in more detail in Chapter 16.

The hi-res screens are divided into screen bytes (horizontal) and lines (vertical). There are 192 lines, numbered 0 to 191, top to bottom, and each line contains 40 screen bytes, numbered 0 to 39 (#\$00 to #\$27) left to right. Thus there are $40 \times 192 = 7680$ screen byte positions.

In hi-res drawing, only 7 of the 8 bits in a byte are plotted (more on this later) and so each screen byte contains 7 bits, or, as they're called when plotted, pixels (let's get away from computerese and call them dots). Each line then can contain $7 \times 40 = 280$ dots. Therefore a hi-res screen can display up to $280 \times 192 = 53760$ dots; that's why they call it hi-res. So far so good. Everything seems to be in logical order but, of course, there are complications; otherwise, why would you need to read this book? For reasons we won't go into, the Apple designers decided to number hi-res lines in a nonconsecutive fashion. For example, line 0 of the Page 1 screen starts at address \$2000 and ends at \$2027. You might then expect line 1 to start at \$2028, right? Wrong. Line 1 starts at \$2400. Line 2 starts at \$2800, line 3 at \$2C00, and so on, producing quite a scrambled

picture. The same situation holds true for the Page 2 hi-res screen although, of course, with different addresses. There is a method to this mad scramble but we need not concern ourselves with the details because the next chapter will describe a way of accessing any screen position without having to refer to the hi-res screen memory map. The map itself is useful, however, so that you will understand how this is done. In addition, situations may arise where you will want to access particular screen positions directly by referring to the map.

USING AN ASSEMBLER

Finally, we get to the subject of an assembler. As mentioned in the *What You Will Need* section at the beginning of the book, you don't have to use an assembler for your assembly language programs but if you don't, I'll reserve a room for you at the home.

The object of writing an assembly language program is, fittingly enough, to produce object or machine code. Object code is a machine language program that consists entirely of bytes stored at memory addresses. Some of these bytes represent numbers and others represent instructions to the operating system. Object code can look something like this:

6000: A9 10 6002: 8D 40 60

The code is interpreted as follows. When the program gets to address \$6000, byte \$A9, an opcode (operation code), tells the computer to store the following number (\$10) in the Accumulator, or A, an area for number storage and manipulation in the microprocessor. The first byte (\$8D) in the next program line is an opcode that instructs the computer to put the number in the Accumulator at memory address \$6040 (note that memory addresses are stored low byte first).

You could enter this code directly from BASIC by POKEing appropriate numbers into appropriate memory locations, remembering first to convert all numbers to decimal. The BASIC program would look like this:

POKE 24576, 169 POKE 24577, 16 POKE 24578, 141 POKE 24579, 64 POKE 24580, 96

The program could also be entered directly from the Apple's Monitor in this fashion:

6000:A9 6001:10 6002:8D 6003:40 6004:60

Here is an assembly language code for the same instructions:

ORG \$6000 LDA #\$10 STA \$6040

ORG \$6000 says start the program at address \$6000. LDA is a mnemonic for LoaD Accumulator (the Apple 6502 microprocessor uses some 56 mnemonics for assembly language instructions). The # prefix says #\$10 is a number, not a memory address. STA is a mnemonic for STore Accumulator and \$6040 is the address where #\$10 is to be stored. This type of code is called a source code and the assembler, when it is instructed to do so, assembles the source code into the object code and usually will display or print both codes together, one next to the other.

Now, imagine a program hundreds or even thousands of lines long. Obviously, a program written in assembly language is more easily written (and read) than one written in machine language. But assemblers have even more useful features, not the least of which are editing capabilities that allow you to go anywhere in the program and change numbers and lines around without having to reenter the whole thing. In addition, assemblers allow the use of labels and comments, both very useful features.

The source code from most assemblers is divided into several fields or columns. First, a line number is displayed for each instruction. These line numbers are not incorporated into the object code—they are there for editing convenience. The next field is reserved for labels, which are optional. When a region of the program is labeled, it can be accessed by referring to the label rather than to a specific memory location. This not only makes the program more readable but also eliminates the chore of changing instructions to reflect new memory addresses when lines are shifted around. The next field is the command field, which contains the opcode and, if required, the operand, the number or address acted upon by the opcode. Finally, there is the comment field, usually delimited by a semi-colon(;). Comments are similar to REM statements in BASIC and are not incorporated into the object code.

13

Let's look at a sample program. When the source code is typed in, it will look like this (the field headings are not displayed by the assembler—they are there for your edification):

Line	Label	Opcode	Operand	Comments
••••	•••••	• • • • • • • • • • •	•••••	• • • • • • • • • • • • • • • •
1	≭ SAMPL	E PROGRAM		
2		ORG	\$6000	START PROGRAM AT \$6000
3	LOOP	LDA	#\$10	;LOAD A WITH #\$10
4		STA	\$6040	;STORE AT \$6040
5		JMP	LOOP	;GO TO LOOP (LINE 3)

Line numbers are entered automatically by the assembler. Line 1 demonstrates another feature of assemblers—an entire line can be a comment if delimited by a *****. Such lines are not incorporated into the object code. When the command to assemble (usually ASM) is given, the object and source codes are displayed side by side:

	1	*SAMPLE	E PROGRAM		
	2		ORG	\$6000	START PROGRAM AT \$6000;
6000:A9 10	3	LOOP	LDA	#\$10	;LOAD A WITH #\$10
6002:8D 40 60	4		STA	\$6040	;STORE AT \$6040
6005:4C 00 60	5		JMP	LOOP	;GO TO LOOP (LINE 3)

The source code and object code are named by you and then saved separately on a disc. The assembler will append a prefix or suffix automatically to one or the other to distinguish which is which. For example, the disc catalog may show the object code as SAMPLE PROGRAM and the source code as SAM-PLE PROGRAM.S. This is how programs appear when assembled using the BIG MAC assembler. Other assemblers may do this differently.

The object code is the machine language program we want to run. The source code is not a program and can't be "run" as such. How do we run the program? Object codes are always stored as binary files. To run, we enter BRUN \langle space \rangle file name (in this case, SAMPLE PROGRAM). This program will be loaded at address \$6000 and will run starting from this location. We can also load the program without running it if, for example, we want just to inspect it. The instructions for this are BLOAD \langle space \rangle file name. To see the program we've loaded, enter the Monitor with CALL-151 and then type 6000L (L for list). The program, along with its assembly language mnemonics but without labels or comments, will be listed starting from \$6000. To run the program now we can enter 6000G (G for go to).

Suppose we decide at some later date that \$6000 is an inappropriate location for this program because we want to use this area for something else. Let's say we now want to store it at address \$4000 instead. We can do this by specifying the address when we BLOAD it, i.e., BLOAD <space> file name,A\$4000. The program will now load at \$4000 and we can run it from the Monitor by 4000G. What will happen when we run it? Disaster! The reason is that the machine language code is nonrelocatable, that is, it can be run only at the location specified by the ORG statement. To see why this is so, let's look at the code itself. The assembly language instruction in line 5 is JMP LOOP. LOOP is a label that refers to address \$6000. Remember that object codes do not deal with labels, only numbers, and

so the assembled code for line 5 is 4C 00 60, which is interpreted by the operating system to mean go to address \$6000. If the program is loaded at and run from \$4000, the 4C 00 60 instruction will be executed faithfully and the program will jump to \$6000, which no longer contains the original instruction. Garbage in, garbage out.

It is possible to write relocatable codes, that is, programs that can be loaded anywhere regardless of the address specified by the ORG statement. Sometimes such codes are necessary, but for our purposes this represents just another complication we can do without. If you want to relocate a program, simply call up the source program, change the ORG operand to the new address, and reassemble.

There is one other aspect of assembler use that should be emphasized so I'll mention it here and remind you of it again in later chapters. Assembly language opcodes are entered as 3-letter mnemonics, designed to help you remember what they stand for. Two such opcodes, BCC (Branch on Carry Clear) and BCS (Branch on Carry Set) are often not helpful in this regard. In the BIG MAC and most other full feature assemblers, these opcodes can be replaced by what are called pseudo-opcodes; e.g., BCC can be replaced by BLT (Branch if Less Than) and BCS by BGE (Branch if Greater or Equal). If your assembler doesn't use these pseudo-opcodes, just use BCC and BCS—there is no difference in the assembled program. Purists might argue against the use of pseudo-opcodes because they are not part of the standard Apple instruction set, but they do make programs easier to write and read. I should also mention at this point that the instruction EQU, which is used to assign a label to a memory address, can be replaced in the BIG MAC and other assemblers by the = sign. If your assembler doesn't allow it, use EQU.

If all this is confusing to you, don't worry about it. Get an assembler, read the instructions, look over some of the programs in this book to get a feel for it, and before you know it you'll be a bona fide assembly language programmer. Now, onward and upward (or, in the case of some programs, downward and acrossward).

Drawing a Shape on the Hi-Res Screen

Of graphics he certainly could write it;

His talent so great he couldn't hide it.

He plotted a shape

- That looked so like a grape
- It was all you could do not to byte it.

rawing a point or a series of points (i.e., a shape) on a hi-res screen involves only three operations:

- 1. Display the screen.
- 2. Clear it.

3. Store a byte in a hi-res screen memory location (\$2000-\$3FFF for Page 1 or \$4000-\$5FFF for Page 2).

DISPLAYING THE HI-RES SCREEN

In Applesoft BASIC, the command HGR can be used both to clear and to display the Page 1 hi-res screen. Similarly, HGR2 clears and displays hi-res Page 2. We can do this in assembly language by accessing built-in subroutines. For example, JSR \$F3E2 is equivalent to HGR and JSR \$F3D8 is equivalent to HGR2. This is fine for clearing and displaying a hi-res screen when speed is not required (i.e., at the beginning of a program), but to accomplish this rapidly we need to write our own assembly language routines.

Displaying the hi-res screen of choice involves accessing what are called soft switches. These are certain memory locations that, when accessed, perform the desired function. Accessing a soft switch means either reading from it (PEEKing in BASIC) or writing to it (POKEing in BASIC). It doesn't make any difference which numbers are read from or written to these memory locations. The access process itself is all that's required. Some soft switches require a read, others a write, and some can be accessed either way (details of soft switches can be found in the reference manuals published by Apple for your particular machine). The soft switches of interest for hi-res graphics are the following:

	Memory Location of Switch				
Decimal	Hex	Function			
49232	\$C050	Turns on graphic mode			
49239	\$C057	Selects hi-res mode			
49236	\$C054	Selects Page 1			
49234	\$C052	Selects full page graphics (Page 1)			
49237	\$C055	Selects Page 2			
49235	\$C053	Selects mixed text and graphics (Page 1)			
49233	\$C051	Selects text mode			

Arbitrarily, I've decided to use Page 1 with full-screen graphics as the screen of choice for all programs in this book. The switches we want to access then are the first four in the table above. These switches can be accessed by either a read or a write. Try this in BASIC or directly from the keyboard:

POKE 49232,0 : POKE 49239,0: POKE 49236,0: POKE 49234,0

The Page 1 hi-res screen will be displayed (you will probably see a screen filled with random dots as these instructions, unlike HGR or HGR2, do not clear the hi-res screens). Now, how do we do this in assembly language? The assembly language instruction equivalent to a PEEK in BASIC is LDA, the mnemonic for LoaD Accumulator (the Accumulator is a part of the Apple's 6502 microprocessor that performs most number manipulations). The LDA instruction is used to load the Accumulator with a byte (LDA #\$08 loads the number 8 into the Accumulator) or with the contents of a memory location (LDA \$2057 loads the Accumulator with the byte stored in location 2057 – note that # preceding a number means it is a number, not a memory location. Because we're simply accessing a soft switch, the particular number loaded into the Accumulator is immaterial.

The assembly language instruction equivalent to a POKE in BASIC is STA (STore Accumulator). This instruction stores the number in the Accumulator in a specified memory location (STA \$4097 stores the number in the Accumulator in location \$4097). Again, when accessing a soft switch, the particular number is immaterial.

Either LDA or STA can be used to access the soft switches we're interested in but I'm going to use LDA throughout (it appears to be the traditional choice among assembly language programmers). Thus, the assembly language code for displaying the Page 1 hi-res screen with full screen graphics is as follows.

ORG

LDA

LDA

RTS

JPROGRAM 3-1

:ASM 1 6000: AD 50 CO 2 6003: AD 57 CO 3 6006: AD 54 CO 4 6009: AD 52 CO 5 600C: 60 6

--End assembly--

13 bytes

That's all there is to it! Running this program (see the section in Chapter 2 on using an assembler) will display the Page 1 hi-res screen (again probably with random dots as the screen is not cleared by these instructions). Let's now use a feature of the assembler to make this program more readable. As mentioned previously, we can assign labels to particular memory locations so that the code reads more like text rather than a series of numbers (this is always nice to do so that when you come back to it three months later you won't wonder why in heaven's name you LDAed \$C050). Here is the same program with labels for the soft switches (JMP is an instruction equivalent to GOTO in BASIC).

]PROGRAM 3-2

:ASM

				1		ORG	\$6000

16 bytes

Symbol table - numerical order:

PGM	=\$6003	GRAPHICS=\$C050	MIXOFF	=\$0052	PAGE1	=\$C054
HIRES	=\$C057			- 10032	TAGET	4 000

Obviously this is a much more readable listing. We're going to use labels as often as we can throughout the book with the idea of eliminating numbers from the source code as much as possible.

CLEARING THE HI-RES SCREEN

Now that we've displayed the hi-res screen, we must clear it before drawing on it. Clearing the screen means turning it all to black, i.e., no dots displayed. The assembly language clear routine is a relatively short program (13 lines), and besides clearing the screen, it also serves as a good example of the use of some common assembly language instructions.

Remember we said before that to draw on a hi-res screen we first display the screen and then store bytes at hi-res screen memory locations. Well, we've already displayed the screen. Now, what bytes do we store and where to clear the screen? It turns out that if you load a hi-res screen location with byte #\$00, that portion of the screen will turn to black, i.e., no dots (the relationship of

other bytes to what appears on the screen will be dealt with later in this chapter). Thus, to clear the Page 1 hi-res screen we load all the screen locations, from \$2000 to \$3FFF, with zeros. The following program shows how this is done.

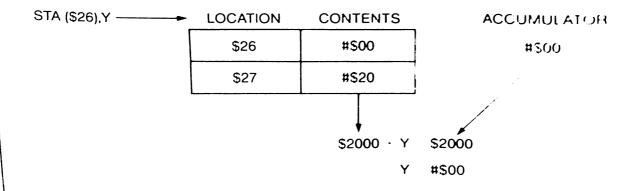

]PROGRAM 3-3

Let's see how it works (assembly language literates or those simply uninterested can skip to the next section). First, byte #\$00 is stored in location \$26 (lines 11 and 12). Location \$26 is called a zero page address because its actual address is \$0026. There's a reason for choosing a zero page address as we'll soon see. Lines 13 and 14 load #\$20 into zero page address \$27. Line 15 loads #\$00 into the Y register (the Apple's microprocessor has two areas other than the Accumulator that can store bytes—the X and Y registers). Line 16 loads the Accumulator with #\$00. Line 17 does the real work. It uses a type of command called indirect indexing, which works only with the Y register and a zero page address (hence choosing a zero page address to begin with). STA (\$26),Y says take the contents of the Accumulator (#\$00 from line 16) and store it in a memory address calculated as follows: go to location \$26 to get the low byte of 19

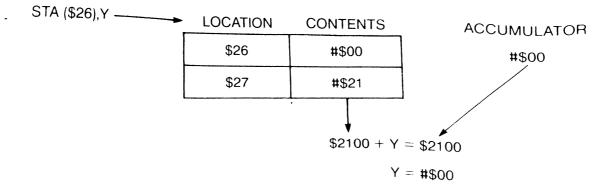

the address and then get the high byte from the next zero page location, i.e. \$27, add the contents of the Y register to get the final address.

Note what has happened. A zero has been stored at location \$2000, the first location of hi-res screen Page 1, turning it black. We're on our way! Line 18 (INY) now increments the contents of the Y register by one. Y now contains #\$01. Line 19 says if Y has not yet reached zero (incrementing the maximum value [#\$FF] by one results in #\$00), branch back to CLR (line 1^{-1}). Line 1^{-1} now calculates the new address as \$2001.

Now we've blacked out the next screen location at \$2001. This continues until Y is incremented to zero, thus blacking out 256 bytes. Then the number located in address \$27 is incremented by one (line 20). Next we do a comparison to see if we're finished. We load the Accumulator with the byte in \$27 and because this will get us into the Page 2 hi-res screen. The command in line 23 of the standard BCC, Branch on Carry Clear) says branch or jump to CLR1 if the program ends. When we branch to CLR1, we load Y again with #\$00 and line 17 puts a zero at location \$2100.

20

Each time 256 bytes are blacked out, \$27 is incremented by one and a new page of memory is selected.

, , ,	\$20 \$21 \$22	00 256 bytes (determined by Y) to \$20FF 00 to \$21FF 00 to \$22FF
	\$3F \$40	00 to \$3FFF 00 Stop — beginning of page 2 hi-res

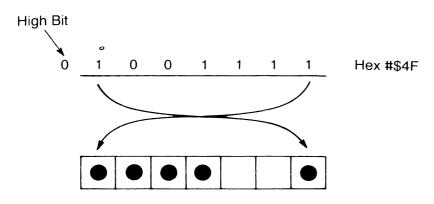

This whole routine takes less than a tenth of a second. Talk about assembly language speed! By the way, if you want to clear hi-res Page 2, place #\$40 in line 13 and #\$60 in line 22. The screen addresses will then be \$4000 to \$5FFF.

DRAWING A SHAPE

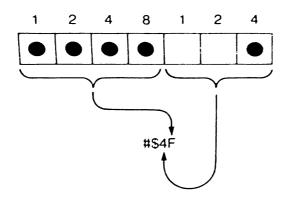

Now that we've displayed the screen and cleared it, let's draw something on it (about time, eh?).

We've seen that if we store a zero at a hi-res screen location, that location turns black. The heart of hi-res drawing is the fact that if we write any byte other than zero to the screen, dots will appear (actually, storing byte #\$80 will also produce no dots—this is a complication we don't need, right? We'll discuss why this happens below). Let's now discuss the relationship of bytes to dot patterns. The details are a bit messy but the application is easy.

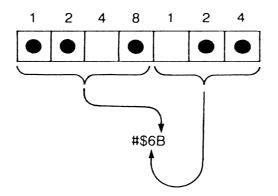

Remember that a byte is a series of 8 bits, each one of which can be off (0) or on (1). You guessed it! If a bit is 0, the screen is black at that point; if a bit is 1, a dot is turned on. But there are complications (you wouldn't want this to be too easy, would you, else how could you impress your friends?). First, only 7 of the 8 bits determine a dot pattern. The leftmost or most significant bit (also called the high bit) is used to select colors for the byte (more on this in a later chapter). This is why storing byte #\$80 will produce no dots. For now, we'll always use 0 as the high bit. Second, the remaining 7 bits are plotted backwards! Why? Don't ask. Let's just see how it works. Here is a byte and the dot pattern that results when this byte is sent to a hi-res screen location.

How does one convert a dot pattern to a byte? Don't fret. It's easy. Place the desired dot pattern in 7 boxes and number the boxes as shown.

Take the rightmost 3 bits and convert them to a hex number. This is the first number of the byte. Then do the same for the leftmost 4 bits. This gives you the second number of the byte. You now have the byte, **#\$**4F, that will give you the desired dot pattern. Let's try another example.

Got it? OK. Let's now write a program that will display the dot pattern in the last example, i.e., the one specified by #\$6B. We're going to put this byte in the first line (line 0) and the first byte (byte 0) of the hi-res screen Page 1 (location \$2000), which is in the upper left-hand corner of the screen. (Be careful to distinguish between the screen byte, which is the location of the horizontal column [0-39 across the screen] where the shape is to be drawn, and the shape byte, which is the byte that determines the dot pattern.)

We can put the shape anywhere on the hi-res screen by changing the screen locations. For example, if we want to plot it one byte over (one byte from the left screen border), the addresses would be \$2001, \$2401, \$2801, etc.

LINE ADDRESS TABLES

There's nothing wrong with this program (it works) but it doesn't address (pardon the pun) the major headache in hi-res plotting, i.e., calculating line addresses. We would like to plot the shape from, say, lines 0 to 5 without bothering about the nonconsecutive nature of the screen line addresses. With the procedure I'm about to describe, one can plot a shape at any line and byte position without having to refer to a huge map of all 7680 screen positions. This will become especially important when we deal with animation, which involves moving shapes around the screen. There is more than one way to solve this problem, but the easiest and fastest way is to use table look-ups. The high byte and low byte of each line address is stored in tables. A line number from 0 to 191 is specified; by looking up the table, the correct line address is retrieved.

The byte position (0-39) also is specified and added to the line address to get the correct screen position. Let's see how it works (see Program 3-6).

There are two tables, one labeled HI for the high bytes and one labeled LO for the low bytes. Each table is 192 bytes long for the 192 line addresses. (The BIG MAC Assembler and some others allow the entry of hex numbers without prescripts using the HEX command; some assemblers do not support this instruction and require the code DFB #\$20, #\$24, #\$28, etc. The ORCA/M assembler uses a DC H' directive; refer to your assembler's instructions.) Suppose we want to plot our man shape at byte 0, lines 0 to 5 as before. We'll use the Y register to hold the byte position and the X register to hold the line position.

LDX #\$00 Line number in X register LDY #\$00 Byte number in Y register LDA HI,X This instruction is called absolute indexing. The Accumulator is loaded with the byte found in location HI + X (remember that HI is a label for a particular address). Because X = 0, the first byte in the HI table (#\$20) is loaded into the Accumulator. STA \$77 The contents of the Accumulator (#\$20) are placed in a zero page location. The Accumulator is loaded with the low byte of the line address, LDA LO,X i.e., the byte in LO + X. Because X = 0, the first byte in the LO table (#\$00) is loaded into the Accumulator. #\$00 is placed in another zero page location. STA \$76 \$76 and \$77 now contain the low and high bytes of the address of line 0 (\$2000). The first shape byte to be plotted is put into the Accumulator. LDA #\$08

STA (\$76),Y We've seen this instruction before in the clear screen routine. It stores the Accumulator contents at a screen address retrieved from the contents of zero page addresses \$76 and \$77 plus Y, the byte position.

We've now plotted the first shape byte at line 0, byte 0. The second shape byte now goes on line 1. To plot on this line, we increment X by one and repeat the above steps with the next shape byte.

INX	Х	now	contains	#\$01
-----	---	-----	----------	-------

LDA HI,X	Loads the Accumulator with the second byte in table HI (HI +
	1 = #\$24)

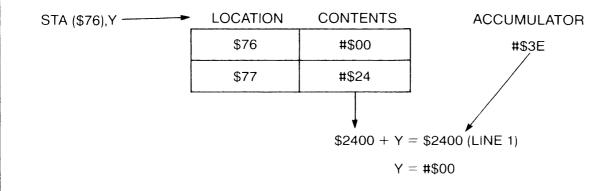

STA \$77 \$77 now contains #\$24.

LDA LO,X Loads the Accumulator with the second byte in table LO (LO + 1 = #\$00).

STA \$76 \$76 now contains #\$00.

LDA #\$3E Loads the Accumulator with the second shape byte.

STA (\$76),Y The second shape byte is plotted at 2400 + Y = 2400 (line 1).

These steps are repeated until all the shape bytes are drawn. We can change the byte and line locations by putting different values in the Y and X registers. For example, to plot the shape starting at screen line 5 and screen byte 4, place 5 in X and 4 in Y. LDA HI,X and LDA LO,X retrieves the line address \$3400. STA (\$76),Y adds 4 to this address to get the desired screen position, \$3404.

Symbol table - numerical order:

LOW DEPTH CLR LO HIRES	=\$1A =\$6005 =\$601F =\$612E =\$C057	HIGH =\$1B XCOUNT =\$6006 DRAW =\$6041 GRAPHICS=\$C050	BYTE PGM SHAPE MIXOFF	=\$6003 =\$6007 =\$6068 =\$C052	LINE CLR1 HI PAGE1	=\$6()()4 =\$6018 =\$606E =\$C054
------------------------------------	---	---	--------------------------------	--	-----------------------------	--

HI and LO refer to the tables in Program 3-6.

Let's examine the program in some detail, because some new elements of assembler use have been added. We need to reserve some space in the program to hold the values for byte, line, depth of shape, and XCOUNT (the use of XCOUNT will be described below). This is done by using the code DS for Defined Storage. Thus, BYTE DS 1 will reserve one memory location somewhere between \$6000 and PGM and label it BYTE (the precise location is displayed in the Symbol Table at the end of the program listing). Also, in keeping with our desire to remove numbers from the source code, we define zero page addresses \$1A as LOW and \$1B as HIGH, and use these labels also in the clear screen routine. (Using \$1A and \$1B as zero page addresses ensures no conflict with DOS commands or any BASIC program we might want to integrate with our assembly language program—see Chapter 16).

We first enter the initial values for line, byte, and depth of shape (lines 31 to 37). Note that the shape depth is added to the starting line number (lines 33 to 35) so that DEPTH will contain the value #\$05 + #\$06 = #\$0B (ADC means ADd with Carry and must always be preceded with CLC, CLear Carry). In the DRAW routine, Y is loaded with the screen byte (line 40) and X with the starting line (line 41). XCOUNT is initially set to zero (lines 38 to 39). Lines 42 to 45 get the line address for the first line to be plotted.

We now need another counter to access the bytes in the shape table but there are no more available—A, X, and Y are being used already. To get around this, we load X temporarily with the value in XCOUNT and use XCOUNT as the shape table counter (X is reloaded with the line number by line 41). Thus, LDA SHAPE,X (line 47) loads A, the Accumulator, with the first byte of the shape table, because X = 0 from the initial value of XCOUNT. STA (LOW),Y (line 48) then plots the first shape byte at line 5, byte 4. XCOUNT is incremented by one (line 49) and now contains the value #\$06. This new line number is now compared to the value in DEPTH (line 52).

To do a CMP comparison, you must first load A with the number to be compared to (line 51). BLT DRAW (line 53) is an instruction that says if the number in A (the line number) is less than the number in DEPTH, go back to DRAW and continue drawing. At DRAW, X is loaded with the new line number (#\$06) and a new address is obtained from the HI and LO tables. X is loaded of the shape table. This is then plotted at the new line by STA (LOW),Y. Thus, program, the screen byte is plotted at screen line 6 and screen byte 4 (in this until the last line plotted is equal to DEPTH. Then the branch at line 53 is not

Compared to the previous program, this program is not only shorter but also easier to read and manipulate. For example, if we don't like the way the shape looks, we can simply change numbers in the shape table. For larger programs with multiple shapes, the advantage of using shape tables becomes even more apparent.

DRAWING SHAPES WIDER THAN ONE BYTE

We've one more topic to discuss before we leave this chapter. Up to now, we've only plotted shapes of width one screen byte or less. Suppose we want to plot a shape that extends over two bytes or more. A slight change in the drawing routine is required. The following program (Program 3-8) plots the shape of a plane that is 2-bytes wide and 5-lines deep.

1	1	1	ł	I	1	1		I	1	1	I	1	1	SHAPE E	
1	2	4	8	1	2	4	1	2	4	8	1	2	4	Screen Byte 1	Screen Byte 2
\bullet	\bullet													#\$03	#\$00
lacksquare	lacksquare													#\$03	#\$00
ullet		ullet	ullet	ullet	lacksquare	ullet	ullet	lacksquare		ullet	lacksquare	ullet		#\$7D	#\$3F
ullet													ullet	#\$01	#\$40
lacksquare		ullet			ullet	ullet	ullet	ullet		lacksquare	ullet	lacksquare		#\$7F	#\$3F

The order of drawing will be:

line 1, first screen byte, second screen byte

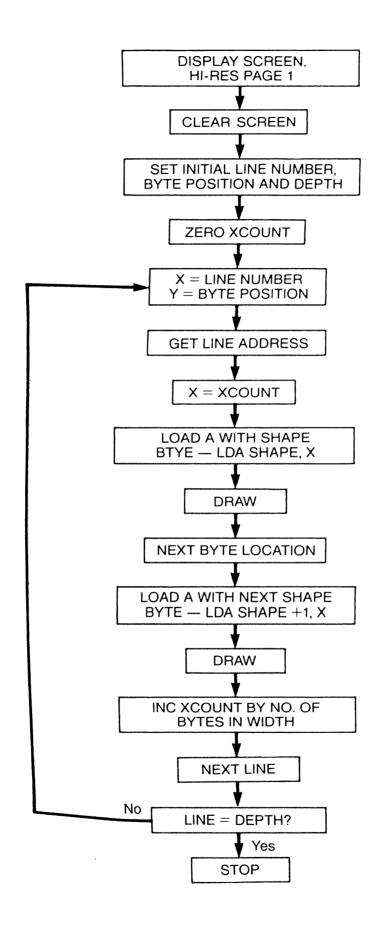

line 2, first screen byte, second screen byte

line 3, first screen byte, second screen byte, etc.

Thus, the order of shape bytes in the shape table is $03\ 00\ 03\ 00\ 7D\ 3F\ 01\ 40$ 7F 3F.

In the DRAW routine, we get the address of the first screen line and first screen byte and plot the first byte of the shape table. Then, on the same line, we increment Y (line 49) so that the next plot (STA (LOW),Y) will be at the second screen byte. LDA SHAPE+1,X (line 50) retrieves the second byte of the shape table for this plot. XCOUNT is then incremented by the number of bytes in the shape width; in this case, two. We then go to the next line by incrementing LINE (line 54) and, because the shape isn't finished yet, we go back to DRAW to reset the screen byte to its initial value (line 40) and obtain the new line address. Now LDA SHAPE,X will get the third shape byte because X = 2 from XCOUNT. INY gets us to the next screen byte and LDA SHAPE+1,X retrieves the fourth shape byte. This continues until CMP DEPTH tells us the shape is finished.

For example, here is a routine for a shape 3-bytes wide: DRAW LDY BYTE LDX LINE LDA HI,X STA HIGH LDA LO,X STA LOW LDX XCOUNT LDA SHAPE,X First shape byte STA (LOW),Y Plot at first screen byte INY LDA SHAPE+1,X Second shape byte STA (LOW),Y Plot at second screen byte INY LDA SHAPE+2,X Third shape byte STA (LOW),Y Plot at third screen byte INC XCOUNT Increment XCOUNT by shape width INC XCOUNT INC XCOUNT INC LINE LDA LINE CMP DEPTH BLT DRAW RTS

We now know how to display any shape anywhere on the hi-res screen using shape tables and line address tables. Following chapters will discuss how to move shapes around the screen using animation routines.

Vertical Animation

There was a young man named Brown On whose brow Program 4-2 produced a frown, "I understand it all right But there's been an oversight What goes up is not coming down."

Computer animation is an illusion. Shapes do not move in a continuous, unbroken path but rather in fits and starts, bit by bit (literally!), or sometimes byte by byte. The illusion is created essentially by speed, in the same way that rapidly changing still pictures create the illusion of movement in movie films. We touched on this before in discussing why the speed of assembly language is essential to animation. But speed is not the only factor. The basic cycle for any animation routine is as follows:

Draw ---> Delay --> Erase --> Move to new position

If the new position is close to the old one and if the process is fast enough, the illusion of continuous movement is created. The reason for the time delay is to ensure that the shape is on the screen longer than it is off; otherwise, excessive flicker will result.

ERASING A SHAPE

Before we get to the actual vertical animation programs, we first have to discuss the problem of the shape erase. We could erase a shape by clearing the entire screen with our clear screen routine but obviously this would be inappropriate if there are other shapes on the screen we want to retain. We could also just store zeros in the general shape area, but there is an easier and neater way. For this we have to introduce another assembly language instruction, EOR (Exclusive-OR). EOR compares a byte, bit by bit, with a byte in the Accumulator. If either bit, but not both, is one, the result is one: otherwise, the result is zero. The result is stored in the Accumulator.

Example:

Accumulator	1 1 0 1 0 0 1 1
EOR byte	0 1 1 0 1 0 1 0
Result in Accumulator	10111001

Let's see how the EOR instruction can be used to erase a shape. Suppose we load the Accumulator with a shape byte from a particular screen location. Then if we EOR the Accumulator with the same shape byte and store the result at the same screen location, the shape will be erased.

		Content of screen location \$NNNN
LDA \$NNNN EOR #\$2D	0 0 1 0 1 1 0 1 (in Accumulator) 0 0 1 0 1 1 0 1	#\$2D
Result	0 0 0 0 0 0 0 0 (in Accumulator)	
STA \$NNNN		#\$00

Pretty neat, eh? But wait, there's more. We can use this same EOR routine not only to erase, but also to draw a shape. All that's necessary is to have a zero stored at the screen location initially.

		Content of screen location \$NNNN
LDA \$NNNN EOR #\$2D	0 0 0 0 0 0 0 0 (in Accumulator) 0 0 1 0 1 1 0 1	#\$00
Result	0 0 1 0 1 1 0 1 (in Accumulator)	
STA \$NNNN		#\$2D

This makes life a bit easier for beleaguered assembly language programmers (us), because now we can use a single routine to both draw and erase a shape. The shape is drawn if the screen location contains a zero, and erased if the screen location already contains the shape byte. Alternate calls to the EOR routine will produce a draw-erase cycle. To recapitulate briefly:

Ordinary draw routine	LDA shape byte
	STA screen location
Draw with EOR	LDA screen location contents (zero)
	EOR shape byte
	STA same screen location

Erase with EOR

LDA screen location contents (shape byte) EOR same shape byte STA same screen location

TIME DELAYS

We now need a routine to introduce a time delay in our programs. For this we can take advantage of certain subroutines built into the Apple's operating system (for details, see the Apple Reference Manual). These subroutines perform many functions, from ringing a bell to printing a character. The subroutine we're interested in is at memory location \$FCA8. When \$FCA8 is accessed, a delay results, the length of which depends on the number in the Accumulator. For example, the following instructions:

LDA #\$40 JSR \$FCA8 (JSR means Jump to SubRoutine)

will produce a delay of approximately 0.01 second. The larger the number in the Accumulator, the longer the delay. In most of our programs, we're going to define the label WAIT as \$FCA8 and reserve a memory location for the number to be loaded into the Accumulator; we'll call this DELAY. We then can load DELAY with a number:

LDA #\$40 STA DELAY

A delay is then produced by:

LDA DELAY JSR WAIT

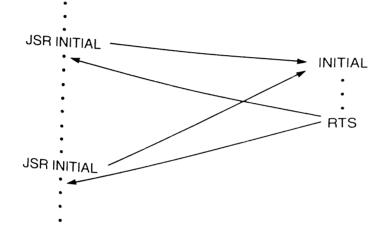

This comes in handy if we want the same delay in several different routines. To see the effect of different delay times, we need change only the value in DELAY. For programs using different delays, we would LDA with the appropriate byte and do a JSR WAIT.

VERTICAL ANIMATION-ONE SHAPE MOVING DOWN

Let's get now to our first vertical animation program. The concept of vertical animation is relatively simple—we draw a shape, delay, erase it, and redraw it either one line down if we're moving down or one line up if we're moving up. We then access the routine repeatedly to traverse the screen (we actually could move any number of lines at a time but a one-line move produces the smoothest results—we're going to use one-line moves for the programs in this chapter).

Our first program (Program 4-1) will move an old friend, the person shape, from the top of the screen to the bottom in a straight line. When it reaches the bottom, the shape will disappear only to reappear at the top for another screen traversal. This will continue ad infinitum until the program is stopped with CONTROL RESET. The program will be using EOR draw routines and also a few things we haven't seen before, so let's discuss some of the details.

First of all, we're going to use the JSR (Jump to SubRoutine) instruction rather extensively. JSR is equivalent to the GOSUB instruction in BASIC. All subroutines called by JSR must end with RTS (ReTurn from Subroutine) in the same way that BASIC subroutines must end with the RETURN instruction.

Although using subroutines does slow a program somewhat (it takes time for any instruction of the second se jump instruction), the time lost in most programs is insignificant and is certainly Overshadow of providing overshadowed by the great advantage, especially for beginners, of providing greater clarity in designing and reading the program. The use of subroutines allows one to divide a program conveniently in two parts—the MAIN PROGRAM and SUBPOURTY of the and SUBROUTINES. The MAIN PROGRAM gives us an overall view of the program's or the main program's or the details. In program's organization, whereas the SUBROUTINES supply most of the details. In the program the program we're about to discuss, for example, one can look at the MAIN

PROGRAM and take in, almost at a glance, what's going on. Program 4-1 starts with the usual display and clear screen routines. In addi-, #\$40 is observed to be a screen routines of the screen routines and the screen routines are screen routines. tion, #\$40 is chosen as the DELAY byte (lines 37 to 38). Let's now look at the MAIN PROGRAM. MAIN PROGRAM in some detail.

CTAR			uctail.					
		INITIAL	A call to the INITIAL subroutine sets the initial byte position, line number, and depth of the shape.					
START1	JSR	DRAW	The shape is drawn with an EOR routine.					
	LDA JSR	DELAY WAIT	A time delay is introduced.					
	LDA LINEA STA LINE		Because the shape is drawn line-by-line starting from the top and working down, to erase the shape using the same EOR-draw routine, the starting line number for the erase has to be reset to its original value; e.g.,					

DRAW
Line 0
Line 1
Line 2
Line 3
Line 4
Line 5
ERASE
Line 0
etc.

LINEA is used as a repository for the original line number—unlike LINE, it is not changed by the DRAW subroutine.

- JSR DRAW This call to the DRAW subroutine now erases the shape since the screen locations already contain the shape bytes.
- INC DEPTH

LDA LINEA

- STA LINE Because we're moving the shape down, we want the top of the shape to begin at a new line, one down from the previous position. To move down a line, we increment, as lines are counted 0 to 191, top to bottom. The new line number is stored in LINE and also in LINEA so that it can be recalled for the erase routine. Note that we do not do an INC LINE because LINE has been altered by the DRAW subroutine. DEPTH is also incremented so that the DRAW routine will draw the entire shape.
- CMP #\$BB This compares the new line number in the Accumulator to the value #\$BB to see if the shape has reached the bottom of the screen. If it has, we want to erase the last drawn shape and start over from the beginning, or at least do something other than allowing the shape to go beyond the screen border. If this happens, the shape may appear in unexpected locations and you will lose control of your program (you could always pull the plug at this point to show who's boss, but let's be more elegant). To see why we selected #\$BB as the comparison byte, we should look at how the shape is drawn as it approaches south of the border.

LINE NUMBE	R									
Decimal	Hex									
185	#\$B9						Ī			
186	#\$BA	•••	••		•		1			
187	#\$BB	• ••	•	•		••		(-:
188	#\$BC	• •	•	•		•				D
189	#\$BD	٠	•			•		•		
190	#\$BE		•			•		•		
191 (bottom)	#\$BF			•		•		•	٠	

The value we want to use in this comparison is the top or starting line of the shape (it doesn't have to be; it's just that we're drawing the shape from top to bottom). Thus, the last shape we want to draw (and erase) starts at line 186 (#\$BA). If we start a shape at line 187 (#\$BB), part of it will be off the screen.

BGE START

- JMP START1 BGE (Branch if Greater or Equal) can be used by some assemblers in place of the normal BCS (Branch if Carry Set). Together with the CMP #\$BB instruction, it says that if the number in the Accumulator (the new line number) is greater than or equal to #\$BB, branch back to START to begin animation from the initial parameters, i.e., the top of the screen. This branch will be taken when the line number reaches #\$BB. If the line number is less than #\$BB, the branch will not be taken and the JMP instruction sends the program back to continue drawing from the last line number.

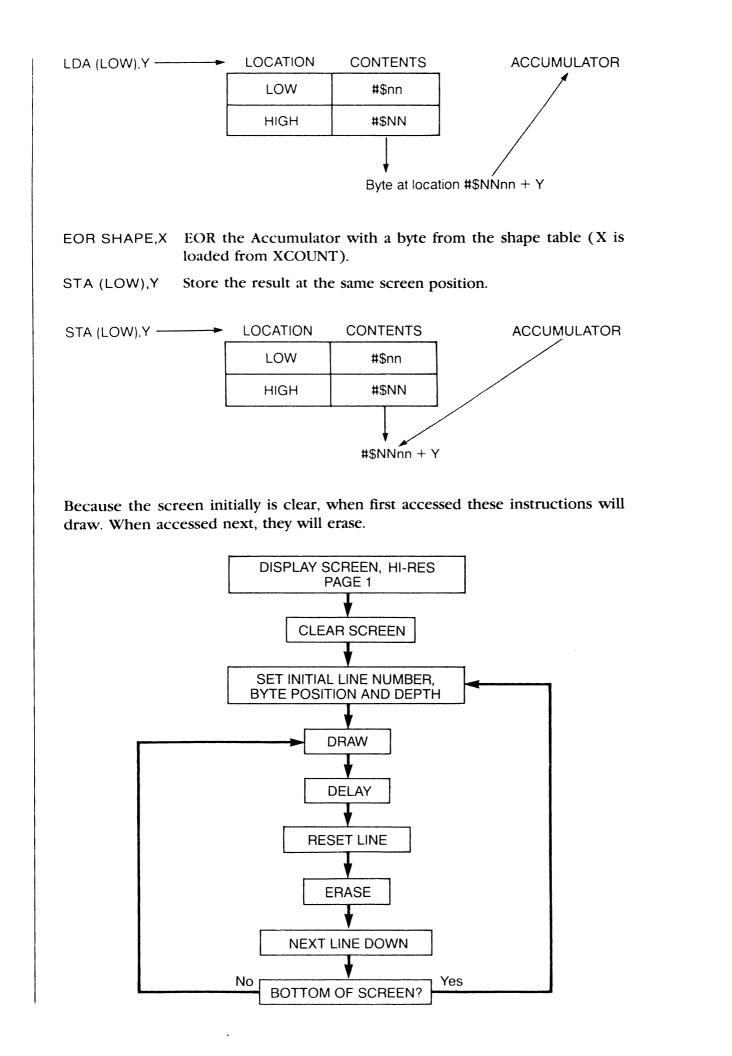

The rule of thumb when using these instructions to test for the bottom of the screen is to (-197 = #SBB). It the screen is to subtract the shape depth from 193 (193 - 6 = 187 = #\$BB). It really isn't all the really isn't all that complicated once you understand the principles involved (right?)

Finally, note that the last JSR DRAW before this comparison is a shape erase. Thus, we are not left with a shape on the screen when we start again from the

The INITIAL subroutine in this program is essentially self-explanatory. It is here we set the initial line number (0 for top of screen) and the screen byte position—I've chosen #\$10 (decimal 16) just to get the shape away from the

The DRAW subroutine should be familiar to you. We load Y with the byte position, X with the line number, use the HI and LO tables to get line addresses, and XCOUNT for accessing the shape table. We then use an EOR routine for

LDA (LOW),Y Load the Accumulator with the byte at the screen position determined by X and Y.

ONE SHAP	PE M	OVIN	G UP						

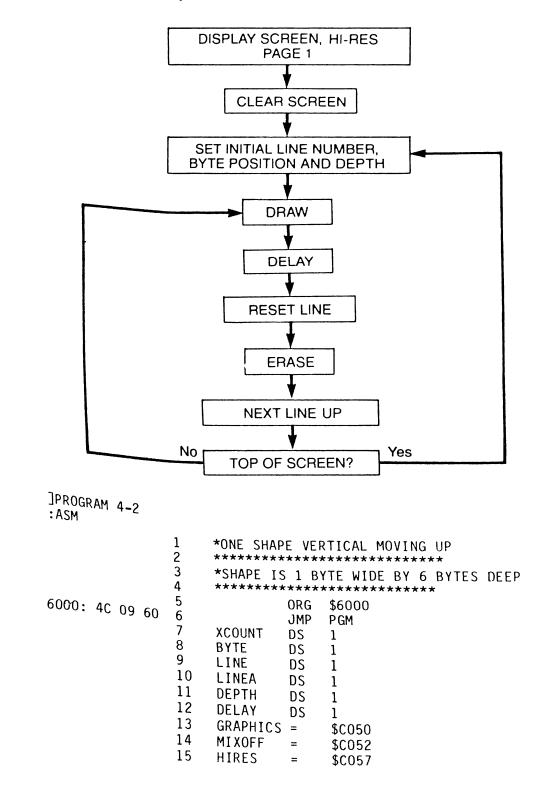

Suppose now we want to move a shape up, from the bottom to the top of the screen (see Program 4-2). There are very few changes that have to be made. First, in the INITIAL subroutine, we set the starting line to #\$BA (186). The shape is 6 lines deep, so the first shape will be drawn from lines 186 to 191, just at the bottom border. Second, in the MAIN PROGRAM, we decrement (DEC) LINE and DEPTH instead of increment, because going up means lower line numbers. Then, to test for the top border, we check if LINE has reached zero:

LDA LINEA STA LINE BEQ START JMP START1

A CMP #\$00 is not needed here because BEQ executes a branch if the result of a previous operation was zero. Thus, when LINE equals zero, the branch is taken

and the shape begins another journey from the screen bottom. These instructions actually stop (and erase) the shape at line 1. This is of little import in our programs, as a one-line difference at a screen border is hardly noticeable.

Finally, the shape has been changed (easy to do just by changing bytes in the shape table) from a person to a sort of spaceship, as it's a bit disquicting to see a person rising without any visible means of support.

DRAW-DRAW ROUTINES

We've seen, in the previous two programs, how to erase a shape using the EOR instruction. Let's call this type of routine DRAW-ERASE. There is yet another way to erase a shape and that is by drawing over it, a process that has advantages as well as disadvantages. We'll call this type of routine DRAW-DRAW. The salient point here is that when a byte is sent to a screen position, the byte (if any) already present at that position is replaced by the new byte.

Example

Contents of screen location \$NNNN #\$17 #\$23

.

LDA #\$23 STA \$NNNN

Let's adapt the DRAW-DRAW routine to Program 4-1, moving a shape down the screen (see Program 4-3). The shape is drawn with an ordinary draw (LDA shape byte, STA screen location) instead of the EOR routine. The shape is moved down one line at a time without any erase routine. Let's follow the shape moving down two lines.

LINE		NEXT LINE DOWN	NEXT LINE DOWN
0	•	•	•
1	••••	•	•
2	• ••• •	••••	•
3	•••	• • • • •	••••
4	• •	•••	• • • • •
5	• •	••	•••
6		• •	••
7			• •

As you can see, each shape byte, as it moves down one line, erases the byte that was there before, thus preserving the shape. As you can also see, something's not quite right. We're always left with the top byte on the screen, because nothing moves into those positions. We solve this problem by providing the shape with a border of #\$00 at the top. Now see what happens.

LINE		NEXT LINE DOWN	NEXT LINE DOWN
0	#\$00		
1	•	#\$00	
2	••••	•	#\$00
3	• ••• •	••••	•
4	•••	• • • • •	••••
5	• •	•••	• • • • •
6	• •	• •	•••
7		• •	• •
8			• •

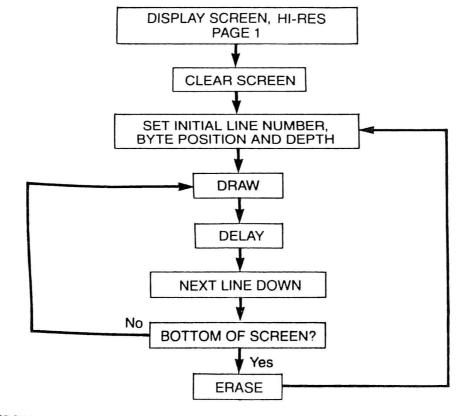

The border is always placed behind the direction of movement and serves to erase the first line of the shape. To introduce the border into the person shape, we add #\$00 at the beginning of the shape table. Thus, the person-shape table with a trailing border is 00083E5D1C1422 (compare to Program 4-1). We must also remember to change the shape depth from 6 to 7 in the INITIAL subroutine. A general rule is that the border size has to equal the maximum shape move. Thus, if we're moving a shape two lines at a time, the trailing border would be two #\$00's.

There is one further complication we have to deal with in programs that use DRAW-DRAW routines. For example, in the program we're discussing, when the shape reaches the bottom of the screen, it will stop and then appear again from the top. Then, because we have no erase instructions, the shape at the bottom stays on the screen. We have to introduce an erase routine to erase the last shape when it reaches a border. For this, we can use our usual EOR instructions in a routine called ERASE. Thus, in the MAIN PROGRAM of Program 4-3,

CMP #\$BA is used instead of #\$BB as in Program 4-1 because this shape is 7 lines deep due to the border (193 - 7 = 186 = #\$BA).

BGE ERASE

JMP START1 Now the comparison tells us if the shape is at the screen bottom, go to the ERASE routine, which erases the shape and then sends the program back to START to continue the animation from the initial parameters, i.e., top of the screen.

]PROGRAM 4-3 :ASM

We mentioned before that DRAW-DRAW routines have certain advantages and disadvantages. As there is no erase cycle as such, shapes animated by DRAW-DRAW move for DRAW move faster and with essentially no flicker. (It should be pointed out that "flicker" is a subjective term and depends to some extent on the image retention characteristics of the monitor or TV you're using—long retention times minimize flicker, whereas short times emphasize it, and retention times vary greatly among different brands of display screens.) On the other hand, DRAW-DRAW requires two routines, one to draw and one to erase the last shape (unless, of course, a shape is to stay on the screen). Also, collision detection is difficult with DRAW-DRAW routines (but only with horizontally moving shapes as we'll see in

In addition, the speed advantage of DRAW-DRAW, at least in simple programs, is more theoretical than practical. If you compare Programs 4-1 and 4-3, you'll see that the shape traverses the screen at about the same speed in both cases. This is because the determining factor is the time delay, which is #\$40 in both programs. So while the speed of DRAW-DRAW is greater than DRAW-ERASE, the speed differential is much less than the time delay. The speed advantage of DRAW-DRAW becomes important only in programs with larger and more complicated shapes where drawing and erasing the shape takes up an appreciable amount of time. It should also be noted that a time delay in DRAW-DRAW

routines is not necessary to reduce flicker by ensuring that the shape is on the screen longer than it is off because the shape is not erased. However, delays are still generally required to slow a program down to a reasonable pace.

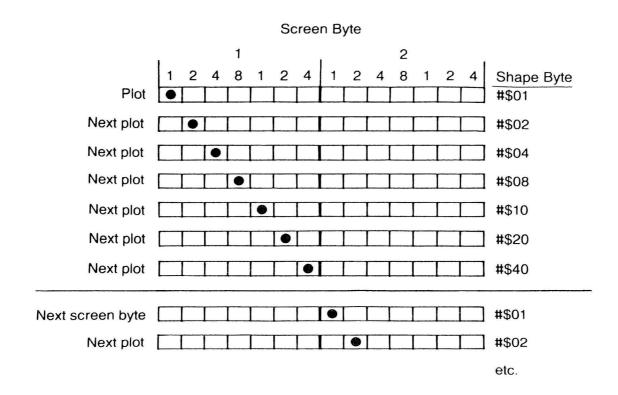

One further drawback of DRAW-DRAW is that it is inappropriate for drawing over backgrounds—this will be discussed in more detail in Chapter 14.

The decision whether to use DRAW-DRAW or DRAW-ERASE routines depends on the particular requirements of the program. If the shape is not involved in collision detection, if you're not drawing over a background, and if more speed and the absence of flicker are desirable, use DRAW-DRAW. If speed and flicker are not problems and collision detection (for shapes moving horizontally) is required, use DRAW-ERASE. The final game program uses DRAW-ERASE routines, mostly because it makes the program easier to write and read, requiring only one draw routine, and speed and flicker are not problems. This should not be construed in any way as relegating DRAW-DRAW routines to second-class status. They are quite useful for smooth and rapid animation and should be kept in mind for your own programs, and indeed for the game program itself; in fact the reader may find it a useful and instructive exercise to modify parts of the final program to DRAW-DRAW. With this in mind, I've included, in later chapfinal program to DRAW-DRAW. With this in mind, I've included, in later chapters, some routines in both DRAW-ERASE and DRAW-DRAW modes. There will be more on program modifications in the last chapter. 54

Horizontal Movement and Internal Animation

Moving a shape horizontal Can cause problems periodontal. The frustrations underneath Lead to gnashing of teeth Side to side and back to frontal.

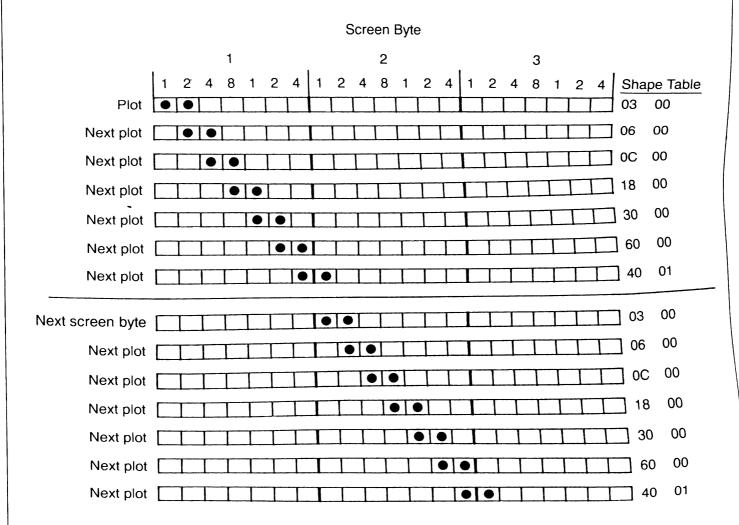

Moving a shape horizontally across the hi-res screen involves the same basic animation principles as vertical movement, i.e., DRAW-DELAY-ERASE-MOVE-DRAW, but a certain complication arises that will become immediately apparent upon examining the following diagram.

THE SEVEN PRESHIFTED SHAPES

Here the shape is a single dot, moving left to right one bit position at a time (we can move the shape any number of bits at a time, but a one-bit move produces the smoothest animation). Obviously what's happening is that every time we move the shape over one bit, the shape byte changes. After moving seven bit positions (one screen byte), the same series of shape bytes is plotted, but now in the next screen byte. Thus, for each shape to be moved horizontally, we need seven different shape bytes (or shape tables in the case of larger shapes). Shapes plotted in this manner are called preshifted shapes. Note that movement results from plotting the different shape bytes and not by changing screen byte positions (except at the screen byte boundaries).

Actually, the example just shown is a special case (one dot at the leftmost position). Let's look at a more general example.

Here we're moving a two-dot shape left to right one bit position at a time. Again, seven different shape tables are required. We also see that the seventh shape is partly in one screen byte and partly in the next. Therefore, in constructing our shape tables, we have to include an extra screen byte in the direction of movement (for one-bit moves). Thus, for a shape one screen byte wide or less, as in the above example, the shape table will cover two screen bytes, and a two screen byte wide shape will require a shape table covering three screen bytes, and so on. This is a general rule, applicable in all cases except the special case of the one-dot shape in the first example.

To summarize, horizontal movement for one-bit moves requires:

1. Seven shape tables for each shape.

2. Shape tables with an extra screen byte in the direction of movement.

Obviously a higher level of complication has been introduced compared to vertical animation, but that's the way it is. There's no way to get around it unless we want to move a shape just one screen byte at a time. In some cases this may be satisfactory, but usually the large distances involved produce an unacceptably jumpy animation.

Let's now look at some actual shape tables we're going to use in our game program. The following diagrams illustrate the seven shape tables for a two-

Shape Number	1	2	4	8	1	2	4	1	2	4	8	1	2	4	1	2	4	8	1	2	4	Shap	e Tat	oles

screen-byte-wide airplane that's going to move horizontally across the screen, left to right, one bit position at a time (the tables are labelled 0 to 6 instead of 1 to 7, because they will be referred to by these numbers in the program to facilitate routines that access them).

The trick to incorporating these shapes into a program is to direct each of the seven shapes to its proper location. The following program (5-1) illustrates one approach to this problem. The program moves the plane shape across the screen from left to right. When the shape reaches the right border, it disappears and then reappears at the left border for another screen journey ad infinitum. Thus, we're also going to discuss in this program tests for the vertical ends of screens. Pay attention to Program 5-1 because we're going to use its routines in our final game program.

TEMP AND SHAPE ADDRESS TABLES

A programming technique I generally strive for is to minimize the number of drawing routines as much as possible. This produces a more compact program, easier to write and understand. Program 5-1 has only a single draw routine for all seven preshifted shapes, and both draws and erases using the EOR instruction.

One way to use a single draw routine accessing seven different shape tables is to store the shape bytes temporarily in an area of memory we'll call TEMP (aren't we clever with our labels), and use TEMP instead of the shape tables in the draw routine. To draw any of the seven shapes, we load TEMP with the appropriate shape bytes and access the draw routine. Another advantage in using TEMP is that for the shape erase, TEMP doesn't have to be reloaded because it already contains the appropriate shape bytes, i.e.,

To load the shape bytes into TEMP, the program has to know where in memory the shape tables are located. To do this, we construct a shape address table and let's label it SHPADR (more clever labelling). This table will store the beginning memory locations of each of the seven shape tables. For example, in Program 5-1, the SHAPE1 table begins at location \$60F5, SHAPE2 at \$6104, SHAPE3 at \$6113, and so on. The SHPADR table will look like this:

SHPADR	F5	(SHAPE1)
	60	
	04	(SHAPE2)
	61	
	13	(SHAPE3)
	61	
	etc.	

Shape address tables contain 14 bytes, 2 for each address of the 7 shape tables (note that the shape table addresses are stored low byte first). Now we

can access each shape table by referring only to SHPADR—this allows us to use a single routine for loading all the shape tables into TEMP. SHPADR and SHPADR+1 will give us the address of SHAPE1, SHPADR+2 and SHPADR+3 will give us the address of SHAPE2, SHPADR+4 and SHPADR+5 will give us the address of SHAPE3, and so on. More specifics about this technique will be discussed below.

For now we have to discuss how the SHPADR table is constructed. This depends on the type of assembler you're using. Full-feature assemblers support instructions that allow the assembler to construct a shape address table directly from within the program. This is illustrated in Program 5-1. Look at the SHPADR table starting at line 22. The instruction DFB #<SHAPE1 loads the low byte of the SHAPE1 table; DFB #>SHAPE1 loads the high byte (the DOS Tool Kit assembler does this backwards - #> for the low byte and #< for the high byte the ORCA/M assembler uses the instruction DC A 'shape table'-a good reason to read your assembler's instructions!). The entire SHPADR table is constructed by the assembler using these DFB instructions for all seven shape tables. If your assembler doesn't have this capability, you have a problem, but one that is not insurmountable, merely inconvenient. In this situation, the problem is you (and the assembler) don't know the shape table memory addresses until after the program is assembled, because assemblers simply start at the ORG and then fill up memory sequentially. The solution in this case is to assemble the program without a SHPADR table, write down the memory addresses of the shape tables, and use the edit feature of the assembler to add the SHPADR table at the end of the program. It doesn't make any difference where in the program the SHPADR table is located, as it is accessed by reference to its label and not to a specific

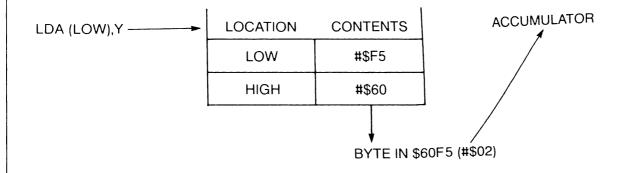

Now that we've constructed the SHPADR table, let's see how it's used to load TEMP with shape bytes. First we have to reserve an area of memory for TEMP. To do this we have to know the total number of bytes in each shape table. The plane shape is 2 screen bytes wide by 5 lines deep. Following the general rule discussed before, the shape table will cover 3 screen bytes. Thus, each shape table will contain 15 bytes (3×5) . Space for TEMP then is reserved by the instruction TEMP DS 15 (line 12).

Before we load TEMP with shape bytes, we have to specify which of the seven shape tables we're going to use. Let's start the screen traversal at the left border with SHAPE1. In the MAIN PROGRAM section of Program 5-1, the shape number is loaded into a reserved memory location I've labeled SHPNO. For reasons that will soon become clear, SHAPE1 is selected by loading SHPNO with 0 (lines 57 and 58). The next line sends the program to the LOADSHP subroutine—it is here TEMP is loaded with the shape bytes. First, the Accumulator is loaded with the value in SHPNO (LDA SHPNO, line 83). At this point, the value is 0. The next instruction, ASL, is a mnemonic for Arithmetic Shift Left (if the contents of the Accumulator are to be shifted, some assemblers require an A Accumulator one position to the left—the result is to multiply the number in the Accumulator by 2, i.e.,

	64						1	Decimal
0	0	0	0	0	1	1	0	6
0	0	0	0	1	1	0	0	12
0	0	0	1	1	0	0	0	24

The result of the ASL instruction is stored in the Accumulator. Because the Accumulator contained 0, the result is still 0. The next instruction (TAX - Transfer Accumulator to X-Register) does what it says—the number in the Accumulator is transferred to the X register. X now contains 0. Now the instruction LDA SHPADR,X loads the Accumulator with the byte found at address SHPADR + X; because X = 0, A is loaded with the value #\$F5, the byte at location SHPADR. This byte is stored in a zero page location, LOW or \$1A. The Accumulator is then loaded with the next byte in the SHPADR table, #\$60, by the instruction LDA SHPADR+1,X. This byte is stored in another zero page location, HIGH or \$1B. LOW and HIGH now contain the low byte and high byte respectively, of the address of SHAPE1 (\$60F5). This completes the process of selecting which shape table is to be loaded into TEMP. The next step is to load TEMP with the shape bytes.

The Y register is loaded with 0 (line 90). The next instruction on line 91 (LDA(LOW),Y) is one we've seen before—indirect indexing. It says load the Accumulator with the byte to be found at a memory address calculated as follows—get the low byte of the address from LOW, the high byte from HIGH, and add the contents of the Y register. The byte found at this address is then loaded into the Accumulator.

The Accumulator now contains the first byte of the SHAPE1 table. The next instruction, STA TEMP,Y stores this byte in the first position of TEMP. The Y register is then incremented by one (INY) and, if it is less than the number of bytes in the shape table (15 or #\$0F), CPY #\$0F (compare Y to #\$0F) and BLT (Branch if Less Than) LOADSHP1 sends the program back to LDA (LOW),Y (line 91) to load the second byte of SHAPE1 into the second position of TEMP, i.e.,

\$60F5 + 0; 1st byte in SHAPE1 loaded into 1st position of TEMP
\$60F5 + 1; 2nd byte in SHAPE1 loaded into 2nd position of TEMP
\$60F5 + 2; 3rd byte in SHAPE1 loaded into 3rd position of TEMP
.

\$60F5 + 14; 15th (last) byte in SHAPE1 loaded into last position of TEMP \$60F5 + 15; stop and return to MAIN PROGRAM

The shape in TEMP is then drawn and erased with the EOR routine we've seen before, except TEMP instead of a shape table is accessed to obtain the shape bytes. We'll discuss the draw routine in more detail below.

Now we would like to draw the next shape, SHAPE2. To do this we increment SHPNO by one (line 64) so that SHPNO now contains the value 1. The LOADSHP subroutine (line 83) multiplies this by 2 (result = 2), and the result is then placed in the X register (line 85). The instruction LDA SHPADR,X (line 86) now loads the Accumulator with the third byte of the SHPADR table (SHPADR + 2), which is the low byte of the address of SHAPE2 (#\$04). This byte is stored in LOW. LDA SHPADR+1,X loads the Accumulator with the fourth byte of SHPADR, which is the high byte of the address of SHAPE2 (#\$61). This byte is stored in HIGH. Thus, LOW and HIGH now contain the low and high bytes, respectively, of the address of SHAPE2. The subsequent instructions load the bytes from SHAPE2 into TEMP in preparation for drawing and erasing. In the same way, SHAPE3 is selected by loading SHPNO with 2, SHAPE4 by loading SHPNO with 3, and so on, i.e.,

SHPNO	ASL	<i>X</i>	LDA SHPADR,X	LDA SHPADR+1,X	SHAPE TABLE
0	0	0	SHPADR + 0	SHPADR + 1	1
1	2	2	SHPADR + 2	SHPADR + 3	2
2	4	4	SHPADR + 4	SHPADR + 5	3
3	6	6	SHPADR + 6	SHPADR + 7	4
4	8	8	SHPADR + 8	SHPADR + 9	5
5	10	10	SHPADR + 10	SHPADR + 11	6
6	12	12	SHPADR + 12	SHPADR + 13	7

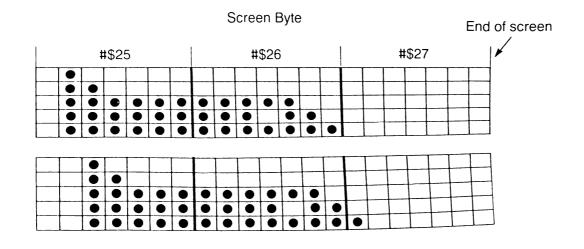

ACCESSING SEQUENTIAL SHAPES AND TESTING FOR END OF SCREEN

Let's look at the MAIN PROGRAM section of Program 5-1. The first instruction accesses the INITIAL subroutine, which sets the initial screen byte and line (0 in both cases) and also specifies the shape depth. Because we want to start with SHAPE1, SHPNO is loaded with 0. We then load TEMP, draw, delay, and erase. The erase is accomplished by the DRAW routine itself because we're using the EOR (DRAW-ERASE) technique discussed in previous chapters. Note that TEMP already contains the bytes of the shape we want to erase and so TEMP does not have to be reloaded with shape bytes for the erase routine.

We're now ready to draw and erase SHAPE2. To do this we first load SHPNO with 1 by INC SHPNO. The next instructions (LDA SHPNO, CMP #\$07, BLT START2) say if the value in SHPNO is less than 7, continue the program at START2; i.e., load TEMP, draw, delay, erase. SHPNO is incremented again for the next shape and so on until SHPNO contains the value 7. At this point, we've plotted the seven shapes (0 to 6 in SHPNO) in the first screen byte.

We now want to start over with SHAPE1 but at the next screen byte. Because SHPNO contains the value 7, the branch BLT START2 (line 67) is not taken and the program skips to the next line (INC BYTE), which increments BYTE by 1. The DRAW routine will now draw in the next screen byte. Before we draw, however, we have to test to see if the shape has reached the right end of the screen because we can't allow the shape to go beyond the screen boundaries. To do this, we load the Accumulator with the value in BYTE and compare it to the value #\$26 (decimal 38). If the value is less than #\$26, the branch in line 71 (BLT START1) is taken and the program continues with all seven shapes drawn in the next screen byte starting with SHAPE1. This continues until the value in BYTE is #\$26, at which point the branch is not taken and the program skips to line 72 (JMP START), which starts the program from the beginning; i.e., the shape now begins its screen traversal in the first (leftmost) screen byte. Because we always follow a draw with an erase, the last shape at the right border is not left on the screen when the shape begins its new journey on the left.

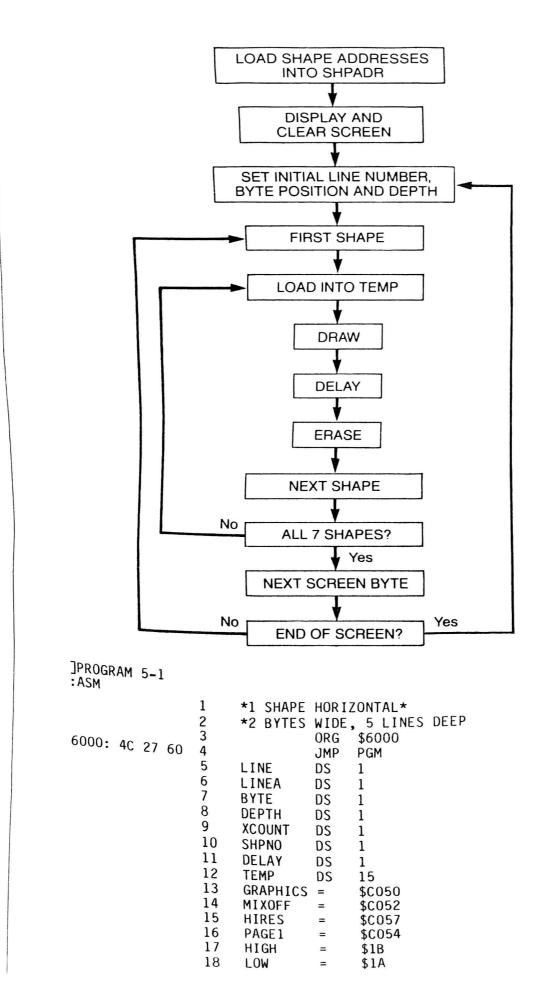

The reason for choosing #\$26 for the end of screen comparison warrants some discussion, because it might seem at first glance that we should use #\$27 (decimal 39) for the comparison since #\$27 is in fact the last screen byte (remember screen bytes are numbered 0 to 39 or #\$00 to #\$27, left to right). The reason for choosing #\$26 becomes apparent when we examine our shape as it approaches the right border.

Here we see the first two shapes drawn starting at screen byte #\$25. It's obvious that once we get past SHAPE1, the other shapes extend into byte #\$27, the last screen byte, as the shape table is 3 bytes wide. If we start at byte #\$26, SHAPE2 to SHAPE7 will extend beyond byte #\$27, i.e., beyond the screen border. So once the value for BYTE reaches #\$26, we want to start over from the left screen position.

This discussion emphasizes the importance of examining a program in great detail before choosing numbers or instructions that seem right. The best way to debug a program is to get it right from the start, admittedly an ideal seldom realized. But if you make prior examination of details a habit, you will save yourself many headaches later on.

Finally, the DRAW routine in Program 5-1 is essentially the same as ones we've seen in previous chapters. It is a DRAW-ERASE type of routine, using EOR both to draw and erase the shape. However, instead of accessing a shape table, TEMP is accessed to obtain the shape bytes. Also, at the end of the routine, LINE is reset to its starting value (from LINEA) in preparation for the next cycle. (Remember that LINE, but not LINEA, is changed in the DRAW routine and so must be reset for the erase cycle because we want to start drawing each shape on the same line—otherwise, it wouldn't be horizontal movement.) Hi-Res Graphics and Animation Using Assembly Language

The more astute among you might wonder why TEMP is used at all, as multiple shape tables can be accessed directly by using a counter (i.e., a number stored in the X register) with the instruction LDA SHAPE,X if the shape tables begin with a single label, SHAPE. If each of the seven shapes contains 10 bytes, the first shape can be called by LDA SHAPE,X when X = 0, the second shape when X = 10, the third shape when X = 20, etc. By manipulating X, all seven shape tables can be addressed. The problem here is that the X register (as well shape tables can be addressed. The problem here is that the X register (as well as the Y register and the Accumulator) can contain only a single byte, which has a maximum value of 255 decimal (#\$FF hex). Thus, if the total number of bytes in all seven shape tables is large, we may have a problem if X cannot be large enough to access all the shape bytes. We would then have to use two or more counters and/or a more complicated draw routine.

Lest you think this an unusual situation, look at the shape tables in Program 5-4. Each shape contains 39 bytes; the seven shapes together contain 273 bytes, and this for shapes that are not particularly large. The use of TEMP solves this problem to a large extent. TEMP also uses a counter (see line 94 of Program 5-1), but only to load a single shape, so the limitation here is that a single shape must contain 256 bytes or less. I suppose it's conceivable that in a state of programming frenzy, you might want to draw and animate horizontally a shape that contains more than 256 bytes, although it would be so large, say 10 screen bytes wide by 30 lines deep, that it would hardly have room to move. This can be done (didn't I say at the beginning that versatility is one of the virtues of assembly language?), but not with the exact routines described here. I'll leave

this to you as a problem you should be able to solve after reading this book (hint: divide the shape into less than 256 byte sections, use multiple TEMPs, and modify the draw routine).

Using TEMP and a single draw routine makes for a neat and compact program but the price we pay is an increase in program execution time because TEMP has to be loaded for each draw. Ordinarily this is not a problem, and it certainly isn't for our game program, but if extra speed is required, we can do away with TEMP and use seven different draw routines, each accessing one of the seven shape tables. This would also eliminate the need for shape address tables and counting shape numbers, and the program flow would be relatively simple—we would just draw and erase each shape in turn, testing only for the end of the screen. The program size would increase, and dramatically so with large numbers of shapes, but the program would run faster. The next program (Program 5-2) illustrates the point—it's the same as Program 5-1 but without TEMP and shape address tables.

As you can see, Program 5-2 is larger than Program 5-1. With more shapes, it would be larger still, but it does run faster, even though it doesn't seem to—the plane traverses the screen in about the same time for both programs but this is because the programs are simple, with only one shape, and so the determining factor is the time delay. The speed difference would be noticeable only with larger and more complicated programs.

SHAPES AT NEW LINE POSITIONS

Before going on to the next section, allow a minor digression—I want to illustrate how easy it is to modify our programs to make them more interesting. In the next program (5-3) we're going to modify Program 5-1 so that the airplanes begin their screen traversal at five different line positions instead of at the same line each time. This makes for a more visually appealing program.

The modifications are fairly simple. In the INITIAL subroutine, the starting line for each traversal is determined by accessing numbers in a table labelled NEWLINE that contains five bytes, one for each new line position. The bytes are selected by LDA NEWLINE,X (line 86) where X contains values 0 to 4. The values for X are loaded from a reserved memory location labeled COUNTER (LDX COUNTER, line 85). Initially, COUNTER is set to 0 (lines 79 and 80) and is incremented by one at the end of each screen traversal (line 75). When the values in COUNTER are from 0 to 4, the branch in line 78 is taken and the shape starts at a new line position. When the value in COUNTER reaches 5, we're at the end of the NEWLINE table and so we want to start over. At this point, the next screen journey (lines 79 to 81). To program more or less line positions, place the desired values in NEWLINE and change the CMP value in line 77 to the number of bytes in the NEWLINE table. DRAW-DRAW

As a special added attraction, for your edification and programming pleasure, I hereby present Program 5-4, which is the same as Program 5-1, except it uses a DRAW-DRAW routine instead of DRAW-ERASE. Let's look at some of the differences between Program 5-1 and 5-4.

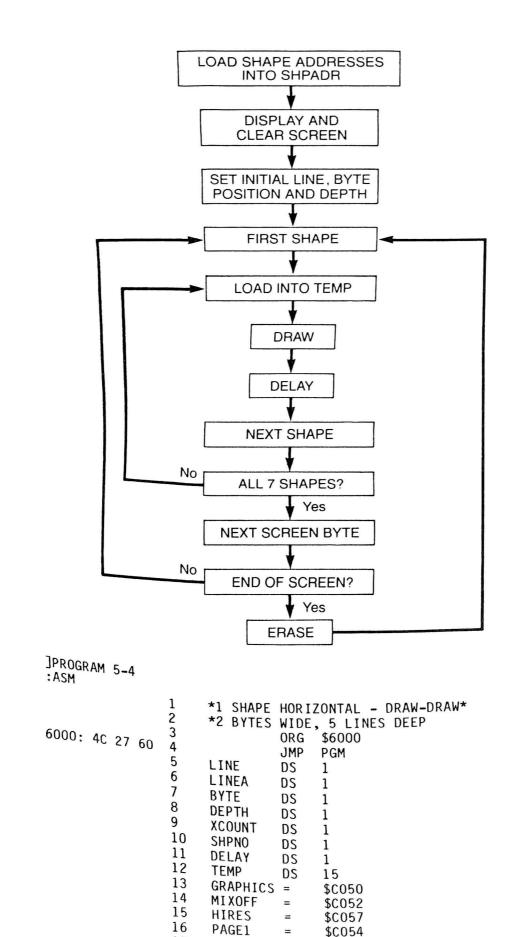

First, since there is no erase step, attention has to be paid to the shape tables to insure that no part of a shape is left on the screen. For vertical animation, we include a border of #**\$**00's equal to the maximum shape move. For horizontal animation, the situation is somewhat different. If we look at the shape tables at the beginning of this chapter, we see that the last shape (number 6) has no bits in the first byte. Thus when we continue with shape 0 in the second byte, shape 6 is completely erased. Fine. But suppose we drew the shape starting with the first column instead of the second. Shape 6 would then have bits in the first byte. If we then continue with shape 0 in the second byte, the bits in the first byte would remain on the screen. Solution? Draw the shapes so the first byte is empty at shape 6 — otherwise, a trailing whole byte of #\$00's will have to be included. This not only would increase the size of the shape tables but would also mean that a shape could not start at a screen border but rather one byte over.

that a shape could not start at a screen border bar table.
Next, the DRAW routine does not use EOR instructions, but rather plots by Next, the DRAW routine does not use EOR instructions, but rather plots by LDA shape byte, STA screen location. Note also that the shape bytes are retrieved from TEMP rather than from the shape tables directly, as in Program 5-1.
Because we want to erase the shape when it reaches the right border in prepara-Because we want to erase the shape when it reaches the right border in prepara-Because we want to erase the shape when it reaches the right border in prepara-Because we want to erase the shape when it reaches the right border in prepara-Because we want to erase the shape when it reaches the right border in prepara-Because we want to erase the shape when it reaches the right border in prepara-Because we want to erase the shape when it reaches the right border in prepara-Because we want to erase the shape when it reaches the right border in prepara-Because we want to erase the shape when it reaches the right border in prepara-Because we want to erase the shape when it reaches the right border in prepara-Because we want to erase the shape bytes on the DRAW routine of Program 5-1; i.e., it erases using the EOR method of plotting because when accessed, the screen bytes already contain the shape bytes to be erased.

bytes already contain the shape bytes to be crased. Finally, let's examine some details in the MAIN PROGRAM. First we initialize the shape position and depth, select the first shape, load TEMP, draw, and then delay. We do not erase as was done in Program 5-1, as the erase is necessary only when the shape has reached the screen border. We continue by testing to see if we've drawn all seven shapes and, if we have, we start again at the next screen byte; this continues until we've reached the end of the screen (BYTE = #\$26). At this point, before going to START to begin a new screen traversal, we go to the ERASE routine to erase the last shape. Note that the last shape is drawn starting in screen byte #\$25 but BYTE contains the value #\$26. So the first line in the ERASE routine is DEC BYTE, which puts #\$25 in BYTE in preparation for the erase. The last line of ERASE then sends the program to START for a new beginning.

guning. If we run Programs 5-1 and 5-4, we see very little difference with perhaps somewhat smoother animation in 5-4 on close inspection. The price we pay for this is a somewhat longer program because of the extra erase routine. Again, the choice of DRAW-ERASE or DRAW-DRAW depends on the program's particular requirements. With a larger, more complicated shape, the smoothness inherent in DRAW-DRAW may become more apparent and, of course, if the program doesn't remove shapes from the screen, the extra erase routine would not be needed. On the other hand, Program 5-4 would not be appropriate if the shape were involved in collision detection or were to be drawn over a background.

Programs 5-2, 5-3, and 5-4 are not incorporated into the final game program because I would like you to use them as starting points to ease you into attempting your own modifications to the game once you've finished Part One. Suggestions for modifications and the problems to consider will be discussed in the last chapter. Hi-Res Graphics and Animation Using Assembly Language

INTERNAL ANIMATION

0

1

Internal animation refers to movement of parts of a shape as the shape itself moves (or doesn't move) around the screen. For example, if we're moving a person shape around, we might want to move his (her) arms and legs to simulate walking or running. This is exactly what we're going to do in the next program (5-5).

The trick to internal animation is simply to have different shape tables displaying various parts of the shape in different positions. This can be done with any type of general movement-vertical, horizontal, diagonal, or curved-or even if the shape is standing still, but it is applied most naturally to horizontal movement, because such movement requires different shape tables anyway. Program 5-5 is virtually identical to Program 5-1 except that the shape is now a person and the seven shape tables display arms and legs in different positions. When these shapes are displayed sequentially, the illusion of walking is produced. The only other change is that a line is drawn along the bottom of the screen (see lines 55 to 65) at screen line #\$B7 (decimal 183) so that the person has something to walk on. You could omit the line and have the person walk on air (with a smile on his/her face?), but both the line and the shape tables are going to be incorporated into the final game program, so let's leave it the way it is. Here are the seven shapes for Program 5-5. (One minor note: one arm is shown pointing up and not moving—this is the arm that carries the gun with which the person is going to shoot at airplanes—who said game designs have to make sense?)

At first glance, it might seem that these shape tables violate the rule of having an extra shape byte in the direction of movement. However, if the shape extends only one bit into the last byte, this is okay because there is room for all seven shapes in the last byte and an extra shape byte is not needed (see shape 6). We could have drawn the shapes over to the left, thus presenting the more usual type of shape tables, but the reason for not doing so is that drawing shapes this way makes it easier to align the fired bullet with the upraised arm, as we'll see in the next chapter.

The principle of internal animation is simple, but the application often is not because greater demands are placed on the artistic talents of the programmer. Even the crude animation of Program 5-5 required much time drawing and redrawing until I could stop the arms from flapping and keep the legs from placing themselves in anatomically impossible positions. Thank goodness for shape tables—they make this kind of tinkering much easier than if the shape bytes were dispersed throughout the draw routines.

You may envy, and with good reason, the type of internal animation found in some commercial game programs. I'm thinking specifically of Olympic Decathlon, which displays athletes running, jumping hurdles, throwing the javelin, and pole vaulting in exquisite silhouettes. These shapes almost surely were derived from photographs of athletes in action and transferred to the computer screen by talented artists, perhaps working with graphic utility programs on mainframe computers in Apple II simulation mode. But don't despair. I myself, devoid of the photographs by tracing the shape onto graph paper and filling in the dots. I even managed, at one time, to write a program displaying unicorns galloping across is hope for anyone.

One final note before leaving this chapter. The line drawing routine in Program 5-5 (lines 55-65) works okay, but there is a faster way to do it. Consider the routine from the program:

LDA #\$7F LN STA (LOW),Y INY CPY #\$27 BLT LN

Now consider the following routine, which draws the same line:

	LDY #\$27
	LDA #\$7F
LN	STA (LOW),Y
	DEY
	BPL LN

BPL (Branch on PLus) executes a branch if the result of an operation is in the range of #\$00 to #\$7F. Thus, the branch is taken until Y is decremented to #\$FF. In both cases, a line is drawn from screen byte positions #\$00 to #\$27, but in the second case, the loop is shorter by one instruction because no comparison is the first for two reasons: first, it works only if we wish a register to go to zero byte #\$27 to #\$05, for example, and second, the loop cannot be initialized with a value greater than #\$7F—this routine for example would not work in the LOADSHP subroutine if the shape were larger than #\$7F. Nevertheless, I mention it because it is an example of good programming technique and while I use the be kept in mind for program optimization where applicable.

Congratulations! You have now learned the basic principles of hi-res drawing and animation. With this knowledge you now should be able to draw any shape and move it around the screen, even in complicated paths (by changing line positions and screen bytes at the same time instead of just one or the other). This knowledge in itself provides you with a powerful tool for a wide variety of applications. The remaining chapters in Part One will deal with aspects of game design and construction together with techniques of more general applicability such as animating multiple shapes discussed in Chapter 6. The chapters in Part Two discuss other aspects of hi-res animation applicable to both game programs and any other type of program where hi-res animation would be useful.

Paddle and Joystick Controls and Multiple Shapes

How's this for a bit of twaddle— Try moving a duck shape with a paddle. If your hand is unsteady The duck will, are you ready? Move with a quite pronounced waddle.

What would a game be without a joystick or paddles? A game without a joystick or paddles. Take my keyboard, please. Seriously folks, some games use the keyboard to control shape movement and initiate actions such as shooting bullets, but joystick or paddle controls are much easier to use and are more entertaining—that's why they exist and why most game programs utilize them. In this chapter we're going to see how to use these hand controls to control vertical and horizontal movement and how to use the "firing" buttons. We're also going to discuss the not insignificant problem of how to display two different moving shapes at the same time. Most of the routines in this chapter will be used in the final game program.

PADDLE AND JOYSTICK CONTROLS

Paddles have rotary knobs and come in sets of two, paddle 0 and paddle 1, each with its own "firing" button. A joystick combines both paddles into a single instrument—the two joystick buttons are equivalent to the paddle buttons. Thus, joysticks and paddles can be used interchangeably although finer control is afforded by paddles. By choosing the appropriate instructions, one can access either paddle 0 or paddle 1 (equivalent to joystick left-right or forward-back) or either button. When using a joystick, it doesn't make any difference which button is chosen but with paddles, one should choose the button appropriate to the paddle—using paddle 0 with button 1 or paddle 1 with button 0 would require a certain amount of dexterity certain not to be appreciated by the program's user. "Reading" a paddle or paddle or paddle of the knob or

"Reading" a paddle or joystick (i.e., determining the position of the knob or stick) fortunately is made easy by accessing a built-in Apple II subroutine located at memory address \$FB1E, which is labelled PREAD in our programs. The number of the hand control you want to access is placed in the X register and a

JSR PREAD then returns a number from 0 to 255 (#\$00 to #\$FF) in the Y register, the particular number depending on the hand control position. Thus:

LDX #\$00 Read paddle 0 (stick left-right) JSR PREAD Returns 0-255 in Y register LDX #\$01 Read paddle 1 (stick forward-back)

JSR PREAD Returns 0-255 in Y register

The number in Y can then be manipulated to select screen byte for horizontal movement or line for vertical movement (more about this soon).

To test whether a button is pressed or not requires only reading soft switches, \$C061 for button 0 and \$C062 for button 1. In conjunction with the opcode BMI (Branch on MInus), the branch is taken if the button is pressed and not taken if the button is not pressed. Thus:

CONT	LDA \$C061 BMI CONT RTS JSR DRAW	If button 0 is pressed, branch to CONT
CONT	LDA \$C062 BMI CONT RTS JSR DRAW	If button 1 is pressed, branch to CONT

That's all there is to it! Let's see now how we can adapt these routines to moving shapes around the screen (for convenience, from now on I will use the term paddle to refer to both paddle and joystick).

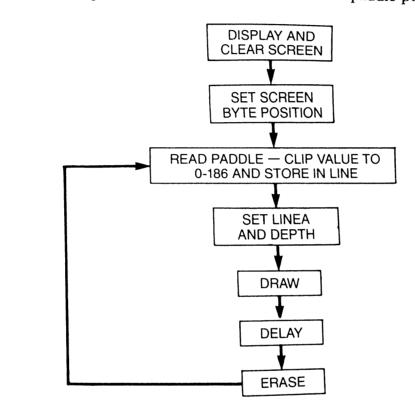

PADDLE CONTROL OF VERTICAL MOVEMENT

The next program (Program 6-1) is essentially identical to Program 4-2 (moving a spaceship vertically), except now we're going to control the space-

ship's vertical movement by paddle 1. Let's examine Program 6-1 in some detail. First, in the beginning of the program, we define \$FB1E as PREAD. Then, in the MAIN PROGRAM, we go to the INITIAL subroutine to set the screen byte. We do not set the line position here because LINE will be determined by the paddle position and we do not set DEPTH here either, as DEPTH depends on LINE. The next instruction sends the program to the PDLE subroutine—it is here that we read paddle 1 and return a value of 0-255 in the Y register (LDX #\$01, JSR PREAD), and we're going to use the value in Y to set the line position. However, as there are only 192 screen lines (0-191), we first have to clip the maximum value in Y to keep the shape on the screen. Because the shape is 6 lines deep and is drawn from the top line down, the maximum line position we want in LINE is 186 (#\$BA)—the shape will then be drawn from lines 186 to 191. The instructions in lines 63 to 67 accomplish the clipping. We compare the value in Y to 187 (#\$BB) and if it less than this, we store the value in Y in LINE. If it is equal to or greater than 187, we store the value 186 (#\$BA) in Y and then store Y in LINE (LDA #\$BA, TAY [Transfer A to Y], STY LINE). Thus, no matter

what the paddle position, LINE will not contain a value greater than 186 and this keeps the shape on the screen.

We then go back to the MAIN PROGRAM and jump to the DEP subroutine which stores LINE in LINEA and also sets DEPTH—remember that while the shape depth is a constant, the value in DEPTH depends on the value in LINE. Back in the MAIN PROGRAM, we draw the shape with JSR DRAW, delay, and erase with JSR DRAW (we're using the DRAW-ERASE protocol). The next instruction sends the program back to PADDLE for another paddle read and we continue in this loop, continually updating LINE from the paddle position.

PADDLE CONTROL OF HORIZONTAL MOVEMENT

In contrast to paddle control of vertical movement where we specify a particular screen byte position and use a paddle read to select the line position, paddle control of horizontal movement involves specifying a particular line position and using the paddle read to select the screen byte position. However, as you might suspect, things are not always that simple with horizontal movement. Remember that in horizontal movement, each screen byte can contain one of seven shapes. Therefore, we not only have to specify the screen byte position by a paddle read, but also which shape is to be drawn. Specifying shapes was relatively easy in previous programs because we started with the first shape and then accessed the other shapes sequentially. With a paddle read, shape and screen byte selection is accomplished by the use of look-up tables. We'll see how this is done in the next program (Program 6-2), which is based on Program 6-2 horizontal movement of a person shape with internal animation (Program 6-2) will be in

In Program 6-2, we're going to use the same shape tables and the line for the will be incorporated into the final game program). person to walk on as Program 5-5 and we're going to control horizontal movement by paddle 0. In the MAIN PROGRAM, we first go to the INITIAL subroutine to set LINE and DEPTH. Then we jump to the PDLE subroutine, which reads

paddle 0 and returns a value of 0-255 in the Y register. We first want to convert the value in Y to a screen byte position. We do this by the instruction LDA BYTETBL,Y (line 85) where BYTETBL is a table consisting of 37 line 37 to 7 #\$24% ing of 37 lines of 7 bytes each, 7 #\$00's, 7 #\$01's, 7 #\$02's, etc., up to 7 #\$24's. A screen byte from 0 to 36 is selected, depending on the value in Y; i.e.,

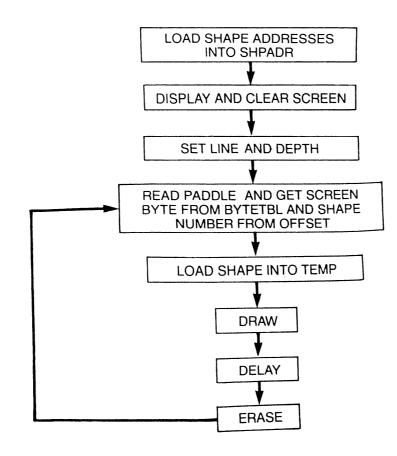

Value in Y	Screen Byte
0-6	0
7-13	1
14-20	2
21-27	3
•	•
•	
245-251	35
252-255	36

The screen byte obtained is then stored in HORIZ (line 86), which will be used in the draw routine to denote the screen byte position. Note that we are accessing only 37 (0-36) screen bytes even though 40 (0-39) are available. This is because Y can contain a maximum value of 255 and, to access all 40 screen bytes, a value of 280 would be needed (40 X 7). We could make the BYTETBL shorter by storing, for example, 6 bytes per line for 40 lines, but there is a reason for having 7 bytes per line as we'll soon see (if you think this is related to 7 the end of the screen, but this would present an unnecessary complication as the last few bytes at the end of the screen is hardly noticeable. The shape can be would be selected, but this is not necessary in our program.

Now that we have the screen byte, we want to specify which of the seven shapes to draw. This is accomplished by using another look-up table. The instruction in line 87 (LDA OFFSET,Y) accesses the table labelled OFFSET which, like BYTETBL, also contains 37 lines of 7 bytes each. But, here, each line 0 to 6; i.e.:

Value in Y	Screen Byte	Shape Number
0		* * * * * * * * * * * * * * * * * * * *
1	0	0
2	0	1
3	0	2
4	0	3
5	0	
6	0	4
7	0	5
	1	6
8	1	0
9	1	1
10	1	2
11	1	3
12	I 	4
13		5
14	1	6
14	2	
		0
252	36	0
253	36	1
254	36	2
255	36	3

The instruction LDA OFFSET,Y loads the Accumulator with a shape number and the rest of the PDLE subroutine loads the shape into TEMP using the same instructions we've seen in Chapter 5. The program then draws the shape, delays, erases, and loops back to PADDLE to update the horizontal position continually. The DRAW routine is the same as in previous programs except that Y is loaded with the value in HORIZ instead of BYTE (BYTE is simply not used in this program).

......Paddle and Joystick Controls and Multiple Shapes

pressed. Also, the program is designed so that only one bullet can be fired at a time; i.e., a bullet on the screen must go off before the next one can be drawn (the program doesn't have to have this feature but what the heck, why not). We accomplish this by reserving a memory location labelled BULON and loading it with #\$00 when a bullet is not on the screen and with #\$01 when one is. Thus testing BULON for #\$00 or #\$01 will tell us the bullet status.

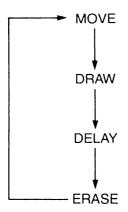

The bullet shape itself is just a single dot, both for convenience and also because it looks fine that way. This simplifies the BTEMP (B for Bullet) loading and also the draw routine. For example, a bullet shape is loaded by retrieving the shape address and loading its contents directly into BTEMP without the need for any counters (see the LOADBUL subroutine). Also, because the bullet shape has a depth of one, the draw routine has no need for XCOUNT, BLINEA, or CMP DEPTH; drawing (and erasing) is accomplished simply by LDA (LOW),Y, EOR BTEMP, STA (LOW),Y (see the BDRAW subroutine). In addition, because the first bullet shape occupies only the first or leftmost bit, the BSHAPE table need only consist of one screen byte—there is no need for an extra byte in the direction of movement.

The bullet is drawn moving up eight lines at a time. The reason for this is not apparent in Program 6-3 but will be when we incorporate the routine into the final game program. The reason is speed. In the game program, we want the bullet to move much faster than a plane moving across the screen. The plane and bullet move once per drawing cycle and the plane moves in 1-bit increments. Moving the bullet up one line at a time, for example, would slow it down so much relative to the plane as to detract seriously from whatever simulation of realism we hope to achieve. Although eight line moves may not be appropriate for most shapes, it works fine with a single dot and the animation simulates a fired bullet quite well.

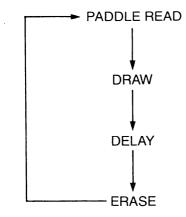

Finally, we have to test for the bullet reaching the top of the screen, at which point it is erased in preparation for the next firing. The bullet starts its screen traversal at line #\$A4, just above the raised arm of the man. If we keep subtracting 8 from this value to get to a line position near the top of the screen, the nearest line to the top turns out to be 4. Thus, we do a CMP #\$05 (line 112); if the line position is less than this, we've reached the top; if more, we continue drawing the bullet.

So much for the easy part, now for the mind-bender. Designing a complicated program, such as one that integrates multiple moving shapes, is best done, at least in my experience, by paying particular attention to the program flowchart, long before getting into extensive program details (this is always a good idea but is especially important for difficult programs). We'll be examining the flowchart for Program 6-4 in detail shortly. A further point regarding multiple shape programs, and one alluded to briefly in the bullet section above, is that each shape has essentially its own program within a program. For example, in Program 6-4, the bullet shape employs BINITIAL, BDRAW, BSHPADR, BHORIZ, etc., while the person shape uses its own set of labels and routines such as MINITIAL, MDRAW, MHORIZ, etc. (M stands for Man; let's face it, a man is more likely to be firing bullets at passing planes than a woman [a sad commentary?]. In any case, P for Person is not used because it is used for Plane in later programs.) The use of these separate routines and labels is a necessity, but a welcome one, because they make the program much easier to write and read.

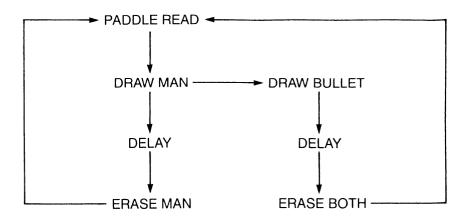

We can modify this for paddle control as follows:

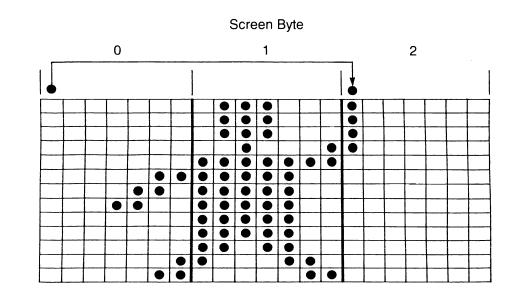

When drawing multiple shapes whose movement is controlled by a paddle, the diagram looks like this (without paddle control, substitute Move for Paddle):

Let's now examine in detail the flowchart for Program 6-4.

Courage, we're almost done. Because we've seen all the routines before, there is no need to discuss the details of Program 6-4 except for one point. The following diagram illustrates the position of the man shape when screen byte 0 and shape 0 are selected by the paddle read.

Assuming the bullet is ready to be fired, i.e., it is not already on the screen, the same paddle read also selects screen byte 0 and shape 0 for the bullet shape. B shape 0 is a single dot drawn at the leftmost bit position (shape byte #\$01) and, if drawn in screen byte 0, will appear to be fired from a position remote from the upraised arm that holds the gun. To align the bullet exactly with the upraised arm, in the LOADBUL subroutine we add 2 to the bullet screen byte position (lines 192 and 193) before drawing. Thus, in this example, bullet shape 0 will be drawn in the leftmost bit position of screen byte 2 and will appear to emerge from the proper position. This relationship holds true throughout the screen range regardless of screen byte or shape number. This is the reason the man shape is drawn the way it is—remember the discussion in Chapter 5 regarding positioning the upraised arm in the leftmost bit position of the third screen byte of the shape table.

We've now gotten through the most difficult part of our discussion of game design. The next few chapters will discuss collisions and explosions, scoring, sound, and in Chapter 10, assembling the final game which involves more or less the same technique developed in this chapter, i.e., a detailed examination of the flowchart, except on a larger scale.

Collisions and **E**xplosions

A scientist from the war games division Designed a game with the ultimate collision. Out of mutual fear Missiles went flying in air, And then, a final nuclear fission.

Collision detection is an integral part of almost every game program and can be used for almost any purpose because once a collision is detected, the program can be instructed to do a multitude of things. For example, a shape can be constricted to the lanes of a maze by not allowing movement past lane boundaries if a collision with these boundaries is detected. In our game program, we're going to detect a collision of a bullet with a passing plane and this will be followed by drawing explosion shapes at the area of impact. In later chapters we will see how to integrate sound and scoring with these collision events.

COLLISION DETECTION

The heart of collision detection is the AND instruction. AND compares each bit of the Accumulator with the corresponding bit of a byte, either a direct value or the contents of a memory location, and returns a value of 1 if both bits are 1; otherwise, the result will be 0. The result is stored in the Accumulator.

Example

Accumulator	00110011
AND byte	0101010101
Result in Accumulator	00010001

Let's see how we can use this instruction to detect collisions. Suppose we have a bullet shape, a single dot, moving up the screen. We want to ask: does the corresponding bit position of the next screen byte position the bullet is going to move into contain a 1 (i.e., a shape) or a 0 (i.e., no shape)? If the screen bit

contains a 0, ANDing the screen byte with the bullet shape byte will return a 0; if it contains a 1, ANDing will return some number greater than 0.

Example

No collision Screen byte in Accumulator (#\$7E) AND with bullet shape (#\$01) Result in Accumulator (zero)	0 1 1 1 1 1 1 0 0 0 0 0 0 0 0 1 0 0 0 0	Shape on Screen 0 1 1 1 1 1 1 1 0 0 0 0 0 0
Collision Screen byte in Accumulator (#\$7E) AND with bullet shape (#\$02) Result in Accumulator (non-zero)	0 1 1 1 1 1 1 0 0 0 0 0 0 0 1 0 	Shape on Screen 0 1 1 1 1 1 1 0 1 0 0 0 0 0

Note that the screen byte itself does not have to be entirely empty for there to be no collision; only the corresponding bit position must be empty. This is exactly what we want. Suppose the screen byte #\$7E corresponds to the bottom line of a plane shape moving left to right. If a bullet is to move into this screen byte and if the bullet shape byte, by virtue of its horizontal positioning, is #\$01, the AND instruction will return a value of 0, i.e., no collision, which describes the situation perfectly; the bullet will pass just to the left of the plane (see Shape on Screen column above). On the other hand, if the bullet shape byte, by virtue of its horizontal positioning, is #\$02, the bullet will appear to hit the plane and the AND instruction will return a value greater than 0, i.e., a collision. (There is an obvious problem here if the high or leftmost bit is set to 1 for either the screen or shape byte as it is for selecting some colors but we'll get to this problem in the chapter on drawing in color—for now, and for all the programs in Part One, the high bit is set to 0).

Now that these principles have collided with your brain cells, we can describe a general routine for collision detection as follows:

LDA Screen Byte	
AND Shape Byte	RESULT IS ZERO IF NO COLLISION
CMP #\$00	
BEQ NOHIT	BRANCH TO NOHIT IF NO COLLISION
JMP COLLISION	GO TO COLLISION IF COLLISION

The CMP #\$00 is not really needed here, as BEQ will branch when the result of the previous operation is zero, but it is included to make the program easier to read.

This general routine presents a problem when we want to detect a collision with shapes moving non-vertically using a DRAW-DRAW protocol. Vertical movement with DRAW-DRAW is okay—the screen byte to be AND'ed is one or more lines above or below the shape and is either empty or not. However, nonvertical movement always contains a horizontal vector and in horizontal movement, the same screen byte is repeatedly accessed for each of the seven shapes. Thus, if we use DRAW-DRAW and the AND test for horizontal movement, the first time we draw a shape we're okay. But when we want to draw the next shape, the same screen byte is accessed (except at the screen byte boundaries) and AND'ed with the shape byte. The screen byte still contains the first shape byte because there is no erase cycle and thus a collision will be detected. In

other words, the shape will continually "collide" with itself. Therefore if a shape with horizontal movement is itself to be used for collision detection, it must use the DRAW-ERASE protocol. DRAW-ERASE works because the shape byte is erased before the collision test. Note that with DRAW-ERASE, the shape byte and not the screen byte is erased. Thus, if the screen byte contains an "on" bit from another shape, this bit will not be erased by EOR Shape Byte because with EOR, 0 + 1 = 1. Thus:

LDA Screen Byte	$\begin{array}{c}1 & 1 & 1 & 0 & 0 & 0 & 1\\1 & 1 & 1 & 0 & 0 & 0 & 0\end{array}$	Shape 1	Shape 2
EOR Shape 1 Byte		#\$07	#\$40
Result in Accumulator	0000001	Shape 2 st	ill in screen byte

As the first shape is both drawn and erased with EOR, the bit from the second shape is always present for the AND test and a collision will result when the first shape enters this bit position.

Let's put all this to work in an actual program. The next program (Program 7-1) is essentially the same as Program 6-3 except now we've drawn a line in the left half of the screen near the top—if a fired bullet hits this line, a long delay will ensue as a collision marker. Shooting the bullet in the right half of the screen will, of course, result in no collision, as there's no line there.

Now to the details of Program 7-1. First, we draw a line in the left half of the screen at screen line position #\$0C (12). There's a good reason for drawing the line at that particular line position as we'll soon see. Next, the program continues in the same way as Program 6-3 until we get to the point where the answer to the questions, "Is the Bullet On?" or "Is the Button Pressed?" is yes.

Now, instead of just drawing the bullet, we first test for a collision; i.e., is there something in the screen bit position where the bullet is to be drawn? The BDRAW routine specifies the line and screen byte where the bullet is to be drawn from BLINE and HORIZB. The instruction LDA (LOW), Y (line 224) loads the Accumulator with the screen byte contents and the next instruction, AND BTEMP, AND's the Accumulator with the bullet shape byte (remember that the value in BTEMP is determined by the horizontal position of the man when the bullet is fired). If the AND result is zero, there will be no collision, the program branches to NOHIT where the bullet is drawn, and the program continues just as in Program 6-3. If the AND result is non-zero, this indicates a collision and the program jumps to COLLISION, which produces a long delay simply as a collision marker, and then initializes the bullet, erases the man, and jumps back for another paddle read. (The BPL instruction [line 238] in the long-delay loop in the COLLISION subroutine continues the delay loop until Y = #\$FF; because Y initially contains #\$10, the LDA #\$FF, JSR WAIT delay will loop 17 times before going to JSR BINITIAL.)

There are a few other details of Program 7-1 we have to consider before going on. First, you might have noticed from the flowchart that the bullet seems not to have been erased after the collision. In fact, it has, because the collision test occurs before the bullet is drawn, not after. In other words, the sequence is draw-erase-test, draw-erase-test, etc. This seems to present another problem, because the bullet is moved up eight lines at a time and thus the last bullet on the screen is eight lines below the collision site. In actuality, however, the bullet is moving so fast that the illusion of a direct hit is preserved. In any event, this is a special situation that arises only when a shape to be tested for a collision is moved large distances between each test. With the more usual smaller moves, say one or two lines or bits at a time, the direct hit illusion is preserved even with slow-moving shapes—the eye can hardly discern whether a collision is on target or one or two bits or lines away. In any case, if this bothers you, you could incorporate the following routine, which uses a test-draw-erase cycle. The shape is drawn in its next position whether or not a collision has been detected—if detected, COLL is set to 1 and this branches the program to COLLISION, which erases the shape before continuing:

LDA (LOW),Y AND BTEMP CMP #\$00 **BEQ NOHIT** LDA #\$01 ;LOAD COLL WITH ONE IF COLLISION STA COLL NOHIT LDA (LOW),Y :DRAW BULLET EOR BTEMP STA (LOW),Y LDA COLL CMP #\$01 BEQ COLLISION ; JUMP TO COLLISION IF COLLISION ELSE RETURN TO MAIN PROGRAM RTS JSR BXDRAW ;ERASE BULLET COLLISION etc.

Next, you will notice that when the bullet is erased after no collision, we access a routine called BXDRAW instead of BDRAW. This is because BDRAW contains the collision test instructions. If we access BDRAW for the bullet erase, LDA (LOW),Y would load the Accumulator with the content of the screen byte, which is in fact the bullet shape byte because the bullet is already on the screen at that location. Thus, if we then do an AND BTEMP, a collision will always be detected even though the bullet isn't hitting anything (except itself!). Therefore we use BXDRAW to erase—BXDRAW is the same as BDRAW but without the collision test instructions.

Finally, we have to discuss how to ensure that the shapes to collide will occupy the same bit positions at the apparent point of collision, a not inconsequential problem. If a shape to be tested for a collision is moved one bit or line at a time, there is no problem, but if the shape moves in larger increments, the collision test may fail even though a collision appears to take place on the screen. For example, the bullet shape in Program 7-1 is tested for a collision at only every eighth line (because it moves up eight lines at a time) starting from line 164 (#\$A4). Thus, a collision will be detected only with shapes that occupy a screen line some multiple of 8 from the starting line—this is why the top line is drawn at line 12 (#\$OC).

Try this for yourself. Draw the top line at screen line 11 or 13 and run the program—the bullet will appear to go right through the line with no collision. However, this appears to be much more of a problem than it is. First, in most cases, shapes are moved only one line or bit at a time and in this situation, every screen line or bit position will be collision-tested. Second, in the case of larger movements, such as the bullet move, all we need do is ensure that the shape to be collided with is in the proper position. In the final game program, for example, bullets are fired at passing planes and all we have to do is draw the planes or

some part of the planes at screen lines some multiple of 8 from the bullet starting line. Remember, we are now expert assembly language programmers and so we can draw shapes anywhere we want!

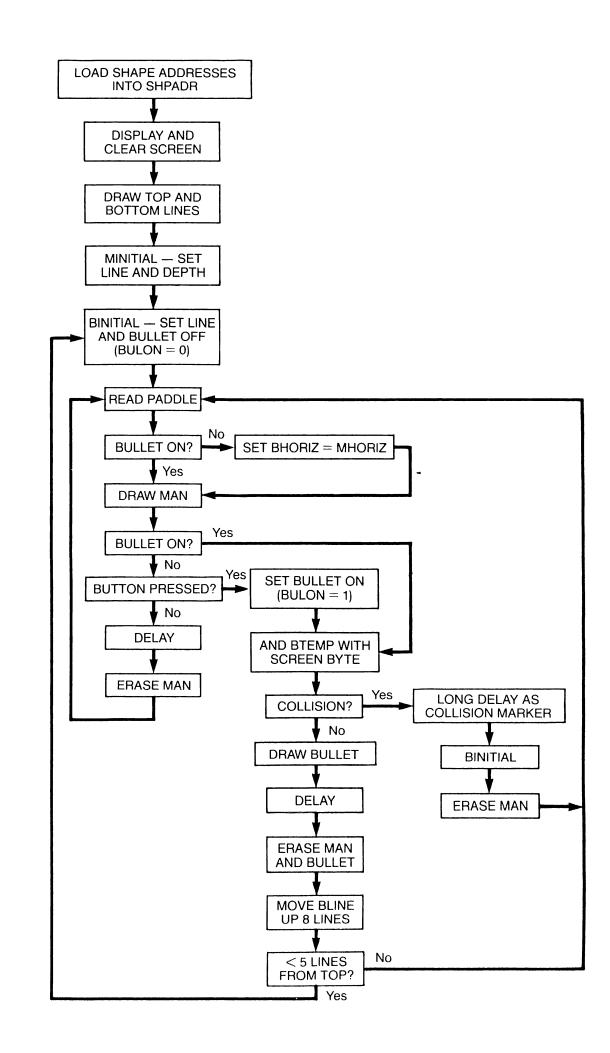

Suppose, however, we can't predict the screen position of a shape to be collided with. For example, suppose we modify the game program so that the planes drop bombs and we want to detect collisions of the bullet with the bombs as well as the planes. The bombs drop in a parabolic curve and at the point of apparent collision with the bullet, may or may not be at one of the multiple of 8 line positions. To get around this, we can use the following BDRAW routine which collision-tests every line position from the last bullet drawn, not just the eighth position up:

	AW LDA BLINE STA BL SEC SBC #\$07 STA CTR	CTR WITH BLINE + UP 7 LINES
* * * * * *	***** TES	COLLISION FROM BL TO CTR ***********************************
COL	LDX BL LDY HORIZB LDA HI,X STA HIGH LDA LO,X STA LOW LDA (LOW),Y AND BTEMP	;TEST COLLISION FOR LINE BL
	CMP #\$00 BEQ COL1	;IF NO COLLISION, GO TO COL1 TO TEST NEXT LINE
COL1	JMP COLLISION	;IF COLLISION, JUMP TO COLLISION ;TEST NEXT LINE UP
	BGE COL LDX BLINE LDY HORIZB LDA HI,X STA HIGH LDA LO,X STA LOW LDA (LOW),Y EOR BTEMP STA (LOW),Y RTS	;STOP TEST WHEN LINE REACHES CTR ;IF NO COLLISION, DRAW BULLET

Try this routine in Program 7-1. You will find that the bullet will collide with any shape regardless of its screen line position.

One final word about shape positions and collisions. If the shape to be collided with is larger than the movement of the collision test shape, the above type of routine would not be necessary. For example, if we want to test for the collision of a bullet with a shape that at every point is at least 8 lines deep, then obviously some part of the shape will always be at a line position that is some multiple of 8 from the bullet starting line.

EXPLOSIONS

Collisions don't always result in explosions but they often do (and they will in our final game program), so let's see how we can modify Program 7-1 to display an explosion when a bullet hits the top line (see Program 7-2).

There are two problems associated with explosion routines. One, how do we draw the explosion and two, where do we draw it? Let's tackle the second problem first.

Obviously we want to draw the explosion at the point of impact. How do we determine where this is? Easy. The horizontal position of the explosion is

obtained from HORIZB, the horizontal position of the bullet at the time of impact, i.e., when the AND test returns non-zero. The vertical position can be determined from BLINE, the screen line position used for the collision test. Actually, in Program 7-2 and in the final game program, the shape that's hit is always at the same line position. In this case, the vertical position of the impact is known beforehand and we simply can specify this line position in our explosion draw routines. Keep in mind, however, that this is not always the case and so in other situations, BLINE or its equivalent must be used.

For example, suppose we modify the game program so that planes appear at several different line positions-to know where to draw the explosion we would use HORIZB and BLINE. In programs involving collisions with multiple shapes, it's also important to know which shape is hit, because (as we'll see in the game program, although not in the programs in this chapter) the first thing we do after detecting a collision is to erase the target shape. Consider a program where a plane is dropping bombs and we want to detect collisions with both. We know the line position of the plane and so if BLINE tells us we're at that line, we know we've hit the plane. If BLINE tells us the collision is below the plane line, we know we've hit a bomb. Now consider a more complicated example. Suppose we have planes appearing at different lines, each dropping bombs. It's conceivable that a bullet may hit a bomb just at the line position of one of the planes. In this case if we rely just on BLINE, we won't know which shape we've hit. To solve this problem we would use both the bomb and bullet shapes as collision testers. If the bomb and bullet hit something, we know we've hit a bomb. If only the bullet hits something, we know we've hit a plane. Let's take this one step

T

ESHAF

ESHAPE :

ESHAPE 3

ESHAPE 4	
ESHAPE 4	

•

•

•

$$PE 1 = 2 = 22$$

$$PE 2 2 = 22$$

further. Suppose the bomb hits something but the bullet doesn't. This means the bomb has hit either the bottom line or the man and we can distinguish between these two alternatives by determining at what line the collision took place.

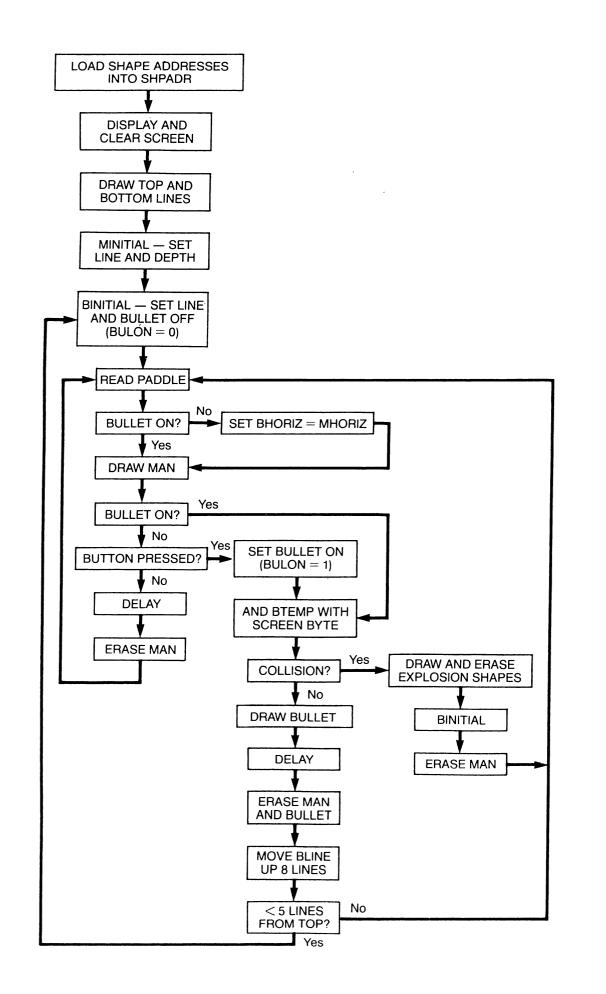

Now let's get to the explosion draw routines. There are many ways to display explosion shapes, from starbursts to splaying of fragments to fireballs, etc. For Program 7-2 and for the game program, we're going to use the fireball type of display. To simulate an explosion, we draw (and erase), at the point of impact, the four shapes (shown on opposite page) in succession—the first two shapes are just random dots, the third is a filled-in "fireball," and the fourth is a larger "fireball."

In Program 7-2, when a collision is detected, the program jumps to the COLLISION subroutine, which then accesses the EXPLOSION subroutine (line 237). Here each of the four shapes in turn is initialized, drawn, delayed, and erased. The program then returns to the COLLISION routine to initialize the bullet, erase the man, and go back for another paddle read.

Each explosion shape has its own initialization routine, labelled INITE1, INITE2, etc., which sets the starting line (ELINE and ELINEA), depth of shape (EDEPTH), and XCOUNT. XCOUNT is specified for each shape because the ESHAPE shape table is accessed in a way that doesn't involve an ESHPADR table, both because it's convenient and because it serves to illustrate that we should not be a slave to any particular type of routine if other routines are equally feasible. In the explosion draw routines, the shape byte is retrieved by EOR ESHAPE,X where X is specified by XCOUNT. Thus, to draw the first shape, we set XCOUNT to zero (lines 323 and 324). Because the first shape contains five bytes, the second shape begins at the sixth position of ESHAPE. Therefore, we set XCOUNT to #\$05 for the second shape (ESHAPE + 5 = sixth byte of table). Similarly, we set XCOUNT to #\$0A for the third shape and to #\$12 for the fourth shape. This type of routine works well if we're dealing with small numbers of shapes and if the shape table is not overly large (we discussed the problem of using this protocol with large shape tables in Chapter 5).

The value for ELINE can be determined from BLINE, the line position of the bullet when the AND test indicates a collision, but as we know where the target is (at screen line #\$0C), this becomes unnecessary in this case. However, the particular values we choose for ELINE depend to some extent on how the shape table is constructed and how we want the shapes to be displayed. This is done more or less by trial and error—we simply try different lines to see what looks right. Explosion shapes 1 and 2 are started at line #\$09 and because a hot fireball always moves up, shape 3 is started at line #\$05 and shape 4 at line #\$01, i.e., at higher screen positions.

The explosion draw routines are the usual DRAW-ERASE type except that we have to use two routines, one for the first three shapes (DRAWE1) and another for the fourth shape (DRAWE2), as the fourth shape is 2 bytes wide but the others only 1. For the erase cycle, we first delay and then reinitialize to reset the appropriate parameters—we then go to the draw routine again to erase. The delay times for each shape are also set by trial and error—the ones I've chosen seem to work best. Finally, as mentioned above, the horizontal position of the explosion is determined by HORIZB (see lines 279 and 298).

One last point. Run Program 7-2 and pay particular attention to the paddle control of the man movement while the explosion shapes are being drawn. You will see, if you look carefully enough, that the man becomes unresponsive to the paddle control until the explosion shapes are finished. An examination of the Program 7-2 flowchart will tell you why this is happening. The entire explosion routine is run before the program branches back for another paddle read. Because the explosion routine uses up some amount of time caused by all the delays between shapes, the program is interrupted momentarily. In many cases, however, including this one and the game program, such an interruption is acceptable because it is of fairly short duration and the man is not moving at some constant speed and thus doesn't appear to "freeze" during the delay. In fact, the user's attention would probably be riveted on the explosion rather than

PREAD

on trying to move the man and so would hardly notice the unresponsiveness of the paddle (it's hardly noticeable even when you're paying attention).

Suppose, however, we have two plane shapes moving across the screen at the same time. When one is hit, the other will freeze in position until the explosion shapes have all been drawn and erased. This would be noticeable and should be avoided. We can solve this problem in the following way. In the EXPLODE subroutine, instead of inserting a delay between each draw and erase, we branch to a routine that will erase the man and read the paddle for another man draw and then return to the explosion. In other words, a program loop will replace the delays. The protocol would then be draw-loop-erase-draw-looperase, etc. The loop cannot use the same paddle read routine that's already in the program because we don't want to go through another bullet draw and collision test, and so we would have another routine that would consist of just erase manpaddle read-draw man. The time for the loop will almost assuredly not be as long as the delays already in the explosion routine and so we would probably have to introduce some time delay between the draw and erase cycles. The exact delays to insert would again be a matter of trial and error-we would just try different values until that second plane moved properly.

This discussion emphasizes an important point about game design (or for that matter any program that is doing more than one thing at a time on the screen) and that is the time delays that are necessary to reduce shape flicker (and sometimes to slow the program down) are exactly the points where one can introduce program loops when one is expanding the program to do more things. We will see, for example, when we get to the game program, that an explosion sound routine is inserted in place of the delay between drawing and erasing the first explosion shape. The sound routine itself provides the necessary delay, and we end up with a program where the explosion looks the same as before, but now with an extra feature.

Scoring, Stopping, and Restarting

A salesman with motives deplorable

Showed an Apple game to a customer adorable.

He said, "This game we'll now play

Scores every which way,

But scoring with you is preferable."

Coring in game programs is almost a law of nature. I can't think of one game program I've tried over the years that didn't have some type of score routine. Of course now that we're experts in hi-res graphics, we can devise any type of scoring display we desire. We can choose our own number shapes, put them anywhere on the screen we want, enclose them in a scoring box with a title, even count in Roman numerals! But let's not get too ambitious. The first program in this chapter discusses a simple scoring routine that's used in the game program. The second program presents a routine of more general utility. We're also going to discuss how to stop a program at a predetermined score and how to start it again from the keyboard.

COUNTING BY ONES

In the following program (Program 8-1), we're going to modify Program 7-2 so that a score display, initially set to 000, increments by 1 each time the top line is hit by a bullet. When the score reaches 100, the program stops and can be restarted by pressing any key. The scoring routine in this program will be incorporated into the game program.

The numbers we'll be using to display the score are simply hi-res shapes depicting digits 0 to 9 (big surprise, eh?). Each number shape is 1 byte wide by 8 lines deep and the 10 shapes are stored in a table labeled NSHAPE. These shapes are accessed and printed in a way we haven't seen before, just for variety's sake and to show off our assembly language dexterity. In the PRINT subroutine, the beginning of each number shape is accessed by LDA NSHAPE,X. Because each number contains 8 bytes, when X = 0, the beginning of the first shape (digit 0) is accessed, when X = 8, the second shape (digit 1) is accessed, when X = 16, the third shape (digit 2 is accessed), etc. Once X is specified, PRINT

then accesses each byte of the designated shape in turn by LDA NSHAPE+1,X, LDA NSHAPE+2,X LDA NSHAPE+7,X. As each byte of the number shape is retrieved, it is printed on a separate line, starting from line 184 to line 191, i.e., just below the bottom line the man is walking on.

The lines where the shapes are to be drawn are specified as direct addresses from the hi-res screen memory map instead of from the line address tables—this saves execution time and program space and is easy to do when dealing with small routines such as PRINT. (In fact, in some programs, if they're large and complicated enough, the use of direct addresses may be called for just to get the program to run fast enough, as a table look-up is a time-consuming process.) The draw instruction has the form STA \$23D0,Y (this is for line 184)—\$23D0 specifies the line, whereas Y specifies the horizontal position where the byte is to be drawn.

To summarize—X specifies the number shape from 0 to 9, the line positions are specified directly in PRINT, and Y specifies the horizontal position.

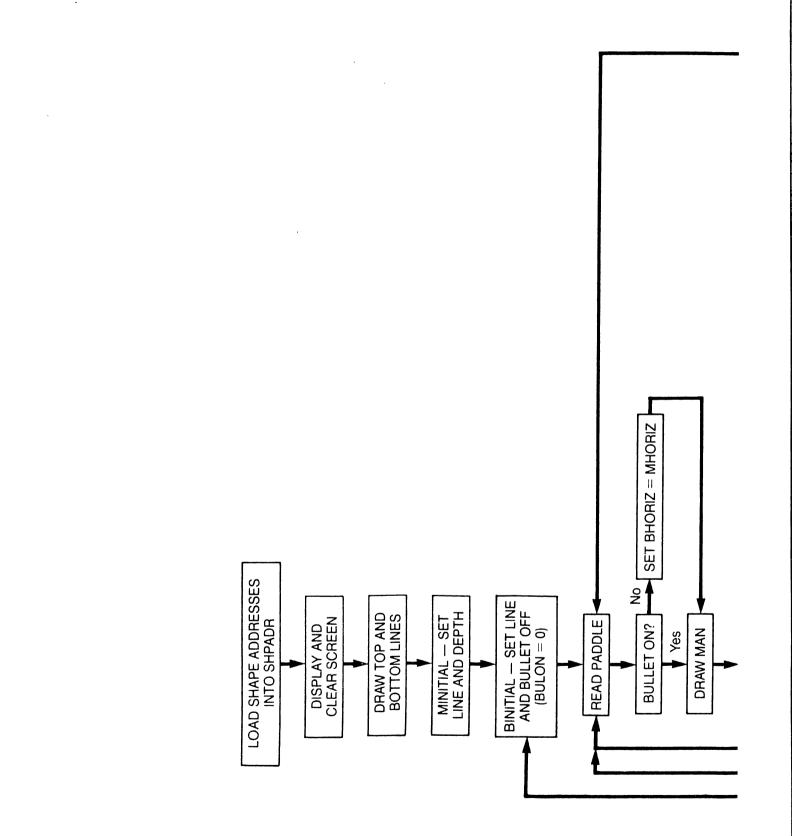

To see how all this works, let's look at the SINITIAL subroutine that prints 000 just below the bottom line at the center of the screen. This is done at the beginning of the program (line 105) to zero the counter. First, the Accumulator is loaded with #\$00 (line 149). Memory locations labelled SUM and COUNTER are also zeroed (we'll get to these later). The next instruction, TAX (line 152), transfers the contents of the Accumulator, #\$00, to the X register. Because X = 0, when we go to the PRINT subroutine the first number shape (digit 0) will be printed. Line 153 loads Y with #\$11, the horizontal position of the first or leftmost digit in the counter display. JSR PRINT then prints 0 at that position. Y is then incremented and another 0 is printed at position #\$12. Finally, a third 0 is printed at #\$13—the loop stops when Y = #\$14. The relationship of Y then to the counter digits is as follows:

#\$11	#\$ 12	#\$13
0	0	0

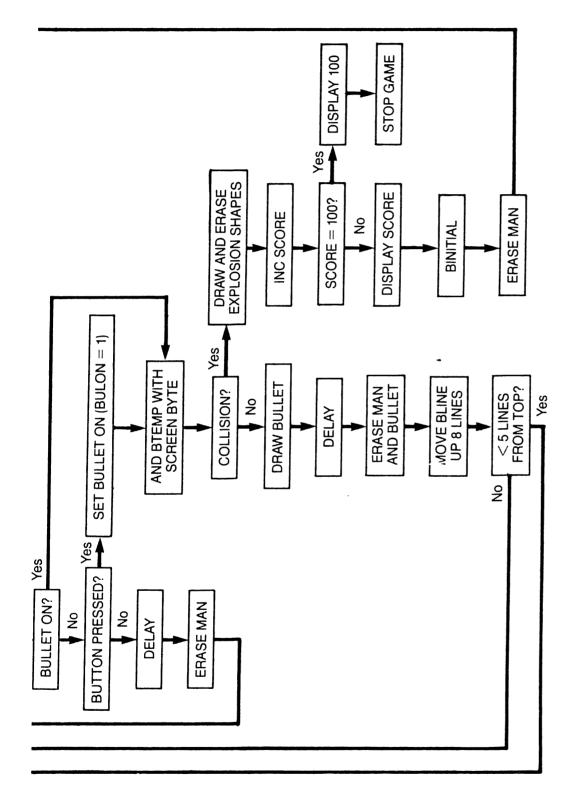

Now that we've zeroed the counter, let's see how we count collision events. Every time a collision is detected, we do a INC SUM and JSR SCORE (lines 252 and 253) in the COLLISION subroutine. In the SCORE subroutine, we load the Accumulator with SUM and compare the value to 10 (#\$0A). If it's not equal to 10, we skip the branch in line 378 and multiply the number by 8. (Remember ASL multiplies by 2 and so three ASLs gives $2 \times 2 \times 2 = 8$; if you don't understand this, return this book for an immediate refund.) We multiply by 8 to access the proper number shape. Thus, when SUM = 1, X = 8 and digit 1 is accessed; when SUM = 2, X = 16 and digit 2 is accessed, and so on. We then transfer the number to X, load Y with #\$13, and print with a JSR PRINT. The number is printed in the rightmost counter position so the counter will now display 001, 002, etc.

Suppose now the number in SUM has been incremented to 10. The branch at line 378 is taken and we go to C10 to increment COUNTER and load the Accumulator with COUNTER (lines 386 and 387). If the number in COUNTER is not equal to 10, the branch in line 389 is not taken and the number in COUNTER is multiplied by 8, transferred to X, and printed at position #\$12 (Y = #\$12, line 394). The middle counter digit will then be 1. We then zero SUM and jump back to SCORE to print a zero in the rightmost position. The counter now

displays 010, which is what we want because SUM = 10. Now when we increment again, SUM will contain 1 and a 1 will be printed at Y = #\$13. Because SUM is again less than 10, the branch to C10 is not taken and COUNTER retains its value of 1. Thus, the counter will display 011. The counting then continues. Each time SUM gets to 10, COUNTER is incremented by 1 and SUM is zeroed; COUNTER is printed in Y = #\$12 and SUM in Y = #\$13.

With this routine we can count to essentially any number simply by specifying other counters, such as COUNTER1 for the 100s column, COUNTER2 for the 1000s column, etc., and modifying the routine to access these counters at the appropriate times; e.g., when COUNTER reaches 10, COUNTER1 is incremented. by 1 and printed in #\$11, and so on. Also, we're not limited by the fact that a memory location can hold a maximum value of #\$FF, as SUM and COUNTER never contain values greater than 10.

STOPPING AT A PREDETERMINED SCORE AND RESTARTING WITH A KEYPRESS

SUM is the counter for the 1's column and COUNTER for the 10's column. Thus, when COUNTER gets to 10, it means the score has reached 100. The branch at line 389 is then taken and the program jumps to STOP1. Here 100 is printed in the counter display and the program then goes to STOP. At this routine, the instruction BIT \$C000 accesses a soft switch that says watch for any keypress. BIT—Compare Accumulator BITS with contents of memory—is an instruction whose main functions I simply do not want to get into and you wouldn't want to either if you saw what it does. Maybe in some future book on advanced techniques (Volume DCMXIII?) I'll discuss it, but for now I use it only to illustrate one of its more arcane but useful features—it can replace LDA or STA to access a soft switch, and it does so without damaging the contents of the Accumulator.

To get back to line 407, BIT \$C000 says watch for any keypress and the next line (BPL STOP) says if no key is pressed, go back and watch again. This loop continues until any key is pressed, at which point the program continues to BIT \$C010, which accesses a soft switch to clear the keyboard strobe (the keyboard holds the last key pressed until either another key is pressed or until the strobe is cleared), and then finally to JMP PGM which starts the program over. Note that we don't have to go back to the program starting line at \$6000 for a restart because everything from \$6000 to PGM has already been done and is in memory. (See flowchart on pages 142 and 143.)

COUNTING BY MULTIPLES AND DECREMENTING SCORE

The counting routine in Program 8-1 fits in well with our game program where we increment the score by 1 every time a plane is hit, and stop the program when we reach 100 (or until 100 planes have appeared). However, it does have some limitations. First, if we want to increment in jumps greater than one, we have a problem. If we increment by 3 and go from 9 to 12, for example, the counter will display 010 because SUM is zeroed after we increment COUNTER. Second, if we want to decrement the score, say by 1 each time the bullet is fired, the routine will not handle this at the 9-0 boundaries (e.g., from 10 to 9), and there would also be a problem if the score is decremented while at 000. The following program (Program 8-2) presents a score routine that solves all these problems.

The SINITIAL and PRINT subroutines are the same in Program 8-2 as in Program 8-1 and again we use SUM as the 1's counter and COUNTER as the 10's counter. The differences are in the MAIN PROGRAM, COLLISION, and SCORE routines. In the MAIN PROGRAM, we decrement the score by one each time a bullet is fired and jump to SCORE to display the count (lines 119 and 120). In COLLISION, SUM is incremented by three each time a collision is detected (lines 254 to 256). Let's see how the SCORE routine handles these changes.

First, we load the Accumulator with SUM and compare to #\$FF. If SUM initially contains zero, as it would if the count were 010, 020, 030, etc., and is then decremented by 1 before we jump to the SCORE routine, we want to change its value to 9 and then decrement COUNTER by 1. Decrementing #\$00 by 1 results in a value of #\$FF. Thus, SUM would contain #\$FF and the branch at line 382 would not be taken. The program would continue to line 383 where #\$09 is loaded into SUM and COUNTER is decremented by 1. We now want to see if the score was at 000 at the time SUM was decremented by a bullet firingobviously at this point we don't want to decrement the score, but rather retain the 000 display. If the score is 000, then both SUM and COUNTER contain zero. Thus, decrementing COUNTER will yield a value of #\$FF and the branch at line 388 will not be taken. The program would continue to line 389 where COUNTER and SUM are both set to zero in preparation for printing 000. These CMP #\$FF instructions then are used for the special situations where either SUM = 0 and is decremented, or where both SUM and COUNTER = 0 and SUM is decremented.

If SUM doesn't contain zero before decrementing or is simply not decremented, SUM will not contain #\$FF, the branch at line 382 is taken, and the program proceeds to C1 (line 392). Here SUM is compared to 10 and if less than 10, the program branches to C10 for the same print routine as in Program 8-1. If SUM equals or is greater than 10, the branch at line 394 is not taken, COUNTER is incremented by 1, 10 is subtracted from SUM, and the count is then printed. Thus, if SUM contains 12, subtracting 10 leaves 2 in SUM. This figure is then printed in the rightmost digit position, and COUNTER will contain 1, which is printed in the middle digit position, producing the display 012.

--	---	---	--	---	--------------------

The protocols presented in this chapter are not the end-all of scoring routines. I know of at least two others that more or less accomplish the same purpose and I'm sure there are still others lurking in programs somewhere. Perhaps you could devise a better routine yourself. Why not give it a try? If you come up with something better, fame, fortune, and members of the opposite sex (or the same sex?) await you.

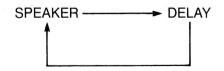

Sound Generation: Explosions and Clickety-Clicks

Clickety-click, buzz and wham Puckety-puckety, pft and slam Pow and bang Whoosh and clang Tinkely-tink, whir and blam.

Dound generation routines are among the easiest to explain but the hardest to apply, at least in game programs, requiring a great deal of trial and error and just plain all around fiddling. This is why other books on assembly language hi-res graphics and most commercial hi-res graphics utility programs omit the subject entirely. Well, there's no getting around it so let's jump in. We'll discuss first the principles of sound generation on the Apple II and then see how to apply these principles to our game program.

THE APPLE SPEAKER AND SOUND GENERATION

Somewhere in your little tan Apple box is what is laughingly called a loudspeaker. Its size is so small it gives new meaning to the term "low fidelity." However, it is capable of producing sounds, if not music. It does this in the following way. The speaker cone is in one of two positions, in or out. By accessing a soft switch located at \$C030, the cone changes position thereby pushing air and producing a sound wave. When the speaker is accessed just once, a click can be heard if you listen carefully. By accessing the speaker in rapid succession, tones are produced; the more frequent the access, the higher the tone or pitch. The basic tone-producing cycle is as follows:

By altering the delay time, different pitches are produced, ranging anywhere from low-pitched clicks (long delay) to high-pitched tones (short delay).

Writing an assembly language program to produce the cycle depicted above is easy to do, especially for us experts, but something else is required lest the tone continue indefinitely (you could always stop the program or pull the plug and lucky Apple IIc owners could always turn down the volume, but let's do it properly). The point is that the cycle has to be interrupted so that we can specify the tone's duration. Let's look at the following program to see how it's done.

```

```

--End assembly--

26 bytes

Symbol table - numerical order:

DELAY	=\$6003	PGM	=\$6004	SOUND	=\$600B	SPEAKER =\$C030
WAIT	=\$FCA8					

The program loads DELAY with #\$60 and Y with #\$02. At SOUND, the speaker is accessed, using BIT instead of LDA just because I feel like it (\$C030 must be accessed either with LDA or BIT, not STA). There is then a time delay followed by a DEY and BNE SOUND. A BNE that doesn't follow a comparison instruction simply means branch if the previous operation results in a non-zero; in this case, branch if Y hasn't reached zero yet. Because Y is now 1, the program branches for another speaker access and delay. DEY now decrements Y to zero so the branch is not taken and the program jumps to START for another round. What's happening here is that the value in DELAY is specifying the pitch, i.e., the time between speaker accesses, while Y specifies the duration. The duration effect is not readily apparent in this program, because at the end of each tone pulse, the program branches immediately back to the beginning for another cycle. If we replace line 15 with RTS, we would then produce a single tone whose duration would be more obviously controlled by Y.

One problem with this type of routine should be mentioned, although it has no bearing on our game program. The duration of the tone depends not only on Y but also on DELAY, because DELAY contributes to the overall execution time for the routine and, thus, a given Y cannot be used to produce different pitched tones of equal duration. (By the way, have you ever noticed that tone is an anagram of note? I only mention this to take your mind off the duration control problem.)

To see the effect of the time delay on pitch, run Program 9-1 with different values in DELAY. A value of #\$60 produces a low, rapid clicking. If we increase the delay, the clicks become lower and slower—#\$90 produces a kind of put-put and #\$BB a sort of hoppity-hop (this is by far the hardest part of writing this book, trying to find adjectives to describe these sounds!). Decreasing the delay produces higher pitches and more rapid clicking. A value of #\$40 produces a buzz, and it's only when we get to #\$30 or below that we hear something that resembles a musical tone. A value of #\$05 results in a very high pitched tone, just barely audible and just barely bearable. Try #\$01 and drive every dog in the neighborhood crazy. Isn't this fun? I hope you're enjoying it, because now we're getting to the sticky part.

INTEGRATING SOUND EFFECTS INTO THE GAME PROGRAM

Although we won't be discussing the game program as such until the next chapter, we know enough about the game already to allow us to apply the principles of sound generation to the development of sound effects. The game itself is relatively simple and this limits our options. The sound effects I've decided to include are an explosion sound when a plane is hit and some sort of sound when a plane is traversing the screen.

One problem with integrating sound effects into any type of program is that any sort of sound, except individual clicks, requires a time delay between speaker accesses and we have to be careful that our sound routine doesn't result in an unwanted program interruption. The solution to this problem is to insert sound routines where program delays already exist.

Let's discuss the explosion sound first. In the game program, as in Program 8-1, a collision sends the program to the EXPLODE subroutine where the explosion shapes are drawn and erased. Remember that between each draw and erase, we inserted a time delay. What I've done is substitute the explosion sound routine for the first delay, i.e., between drawing and erasing the first explosion shape. In other words, the sound routine itself provides the delay—in this way we've added an extra feature to the program without altering its execution time. The sound routine itself is listed below:

```
SOUND LDY #$02
SOUND1 BIT SPEAKER
LDA #$60
JSR WAIT
DEY
BNE SOUND1
RTS
```

This routine produces a single tone with a delay of #\$60 between speaker accesses. The total delay for this routine can be calculated as follows. The LDA #\$60, JSR WAIT is accessed twice (Y = 2). Two times #\$60 equals 2 times 96 = 192 or #\$C0. The original delay time was #\$BB or 187. Thus, even adding a little

extra time for the execution of the sound routine, we see that the total delay is very close to what we had originally.

It might seem, on paper at least, that a single tone is hardly appropriate for an explosion sound but if you run the game program you'll see that it works. That's why so much fiddling is required—what looks bad on paper may be perfectly alright in a program and, unfortunately, vice versa.

In spite of the fact that the routine works, I'm sure that with a little extra fiddling, you or I could come up with something better. Instead of me doing it for you, here is an opportunity for you to display your expertise and imagination (if you think I'm trying to wriggle out of this, you're right). How can we do this? Well, we could try to alter the tone by raising the pitch and duration. Doing this would not increase the total delay time because raising the pitch means less delay between speaker accesses. We could try inserting other tones in other program locations—obvious places would be the time delays between drawing and erasing the other explosion shapes. We could try—well, as I told you in the beginning, there's a lot of trial and error involved in this process, and so on some cold February night, with a blizzard raging, nothing on television, the kids asleep, the dog at the vet, and your wife/hubby in Hoboken for the annual meeting of the International Computer Widows/Widowers Association, give it a try. You have nothing to lose except your sanity.

Now we get to the plane sound. The plane as drawn looks like it's jet- or rocket-powered and so one might imagine that we should strive for something like a whooshing sound. However, computer game programmers are allowed the equivalent of poetic license, which means if it's too hard, we'll do something else. The plane is, in fact, powered by an electric motor. Why? Because I say so – after all, I am its creator (there's nothing like learning assembly language to give one a feeling of omnipotency)-and besides, the motor sound effect somehow seems to work. The sound we want then is a kind of clickety-click (there are those adjectives again) and one way to accomplish this is by clicking the speaker just once each time a plane is moved one bit position. The delay between clicks is accomplished by the program itself as it loops from one plane move to the next. However, when I tried this in the game program I wasn't entirely satisfied because the clicks were too rapid, and so I decided instead to have the speaker click every other plane move. The technique for doing this illustrates a method generally applicable to any situation where we want to access a routine every other cycle, so let's discuss the details.

The Apple II microprocessor contains another register besides the Accumulator, X, and Y, called the Status Register, which can also hold just a single byte. In contrast to the other registers, however, the Status Register is not used to store numbers per se, but rather to indicate certain conditions by having each bit contain a 1 or 0. I'm not going to discuss all the functions of the Status Register bits but the one bit I do want to discuss is called the Carry bit. One function of the Carry bit is to indicate an overflow when a number is added to #\$FF in the Accumulator. For example, adding #\$01 to #\$FF zeros the Accumulator and sets the Carry bit to 1. This is why the instruction ADC (ADd with Carry) requires a prior CLC (CLear Carry) and why SBC (SuBtract with Carry) requires a prior SEC (SEt Carry). Another function of the Carry bit is as an indicator in comparisons. For example, CMP compares a value to the value in the Accumulator. If the value in the Accumulator is less than the compared value, the Carry bit is cleared (0); if more, the Carry bit is set (1). This is why the pseudo-op BLT (Branch if Less Than) is used in some Assemblers in place of BCC (Branch on Carry Clear), and BGE (Branch if Greater or Equal) in place of BCS (Branch on Carry Set).

Now we're ready to see how we can use the Carry bit for our every-other-cycle click routine.

The instruction LSR (Logical Shift Right) moves each bit in the Accumulator one position to the right—a zero is moved into bit 7 and bit 0 moves into the Carry. Note that some assemblers require A in the operand column, i.e., LSR A.

LSR can be used to test if the number in the Accumulator is odd or even. If even, bit 0 (this is the 1's column) must contain 0 and after LSR, the Carry bit will be clear; if odd, bit 0 must contain 1 and after LSR the Carry bit will be set. Thus, a BCC will branch the program if the number is even and not branch if the number is odd (here we're using BCC instead of BLT because the standard mnemonic reminds us what the instruction is doing).

Now let's see how to use LSR to alternate the speaker clicks. First, somewhere in the beginning of the program we define a memory location DE. Then, in the MAIN PROGRAM at the point where we draw a plane with JSR PDRAW, we include the following routine:

JSR PDRAW	;DRAW PLANE
INC DE	
LDA DE	
* * *	;CARRY = 0 IF DE IS EVEN
LSR	;CARRY = 1 IF DE IS ODD
BCC BUL	;SKIP NEXT LINE IF CARRY $= 0$
BIT SPEAKER	;CLICK SPEAKER
etc.	

BUL

Every time a plane is drawn, DE changes from odd to even or vice versa and thus the speaker is accessed only every other plane draw. Because this routine clicks the speaker just once, no time delay is involved (except for the time it takes to run the routine) and the program execution time is not noticeably affected. DE does not have to be set to any particular number in the beginning of the program, as the actual value in DE is immaterial for the odd-even cycle. Note also that DE never fills up because when it reaches #\$FF it simply wraps around to #\$00. In addition, notice that we first load DE into the Accumulator and then do an LSR on the Accumulator contents. The LSR instruction can have a memory location as the operand, but if we perform an LSR DE directly without loading DE into the Accumulator, DE would itself be changed and this would interfere with the odd-even cycling.

This brings us to the end of our preparatory chapters. In the next chapter we will see how to assemble the final game program.

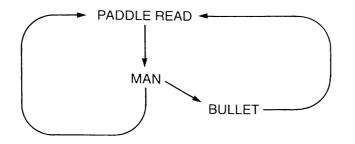

There once was a girl from Sydney Who could . . . (never mind).

ur goal is finally in sight. All we need do now is to take our expert knowledge of assembly language programming and the routines we've already developed and assemble them into the final game program, but this is easier said than done as we'll soon see.

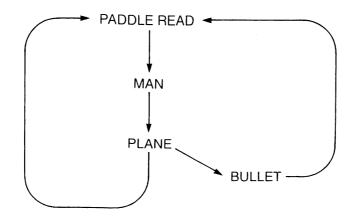

Essentially what we're going to do is merge Programs 8-1 and 5-1, and add sound routines and a few other embellishments. Before we do this, however, a brief description of the game is in order. A man will move along a bottom line, his movement controlled by a paddle or joystick. Planes will appear, with appropriate sound effects, one at a time near the top of the screen, moving left to right all at the same screen line position. A bullet can be fired by pressing the paddle or joystick button. If a plane isn't hit by a bullet, it continues to the end of the screen where it is erased and a new plane then reappears for another screen traversal. If a plane is hit, it explodes with a (sort of) bang, the score is incremented by 1 and another plane then appears at the left border. The game stops when the score reaches 100 or when 100 planes have appeared. Thus, if 10 planes are missed, the game will stop at a score of 90. In this way, a player can tell how close he came to the ideal of hitting all 100 planes. The game can be restarted by pressing any key.

Now to the heart of the matter. As mentioned in a previous chapter, when dealing with a relatively complicated program, it is essential to design the flowchart first, leaving the details to later. The fact that we already have most of the details is of no matter. It is merely a consequence of the fact that this book is a teaching exercise—an experienced programmer would start with this chapter first and work backwards, so to speak, to fill in the details. The main problem in designing a game program is ordering the routines in such a way that the desired simulation is achieved. Remember that a computer can do only one thing at a time and in the final program we might want to simulate, at some points at least, simultaneous events, and some events must follow or precede others. We have to consider which shapes to draw first, which to draw last, when to erase, where to insert the paddle read, score, and explosions, etc. The ordering of routines then is the salient dictum.

Remember that in Chapter 6 we discussed for the first time how to design a program with two shapes moving at the same time, the man and bullet. The overall design can be depicted as follows:

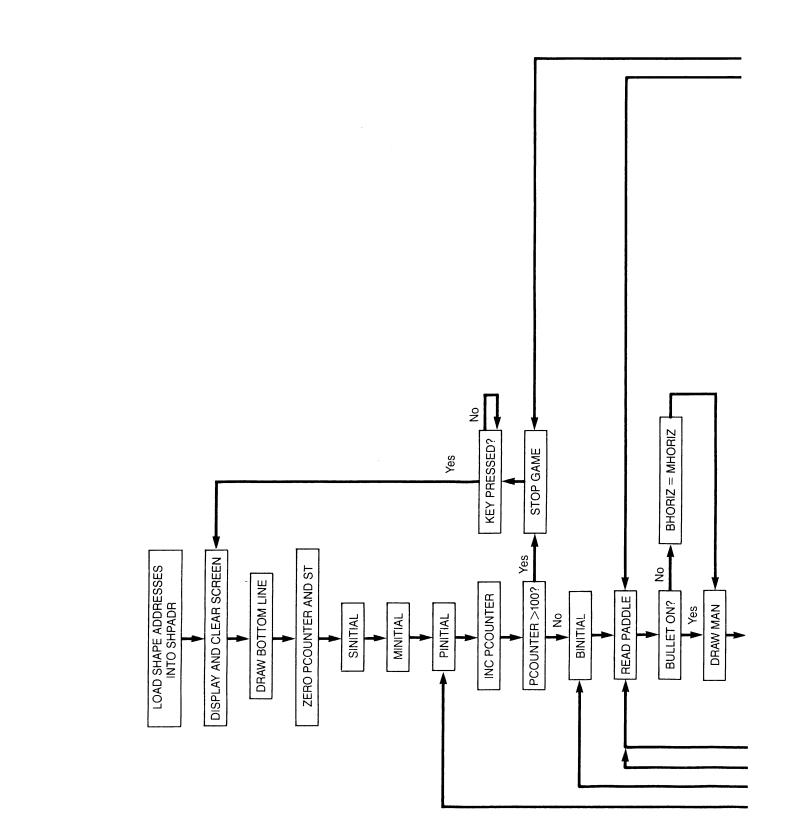

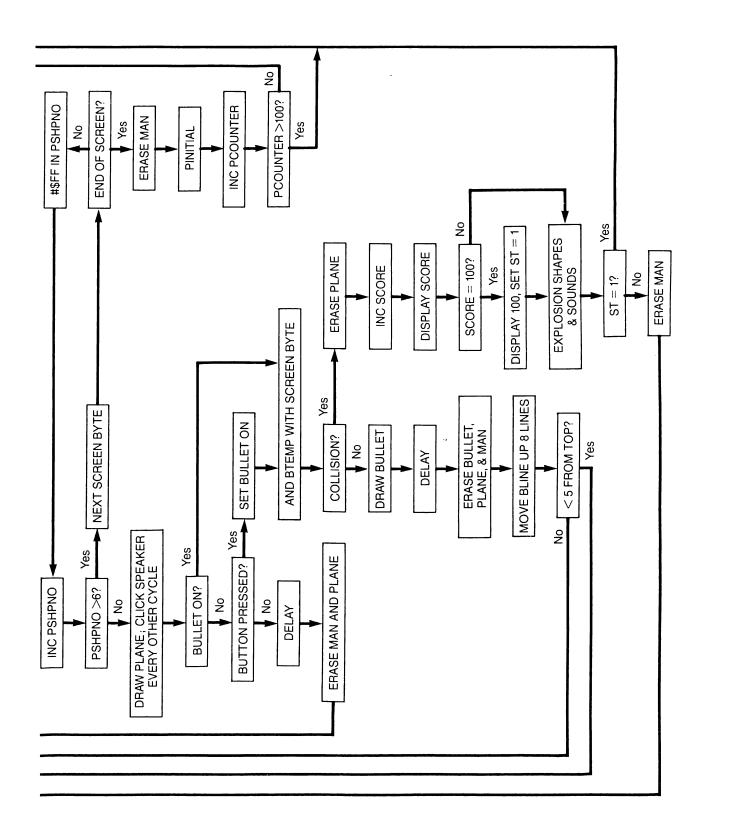

The program continues in this loop indefinitely even if a bullet isn't drawn or if the paddle doesn't change position. The important point is that we created the illusion that the bullet moves at the same time the man's movement is controlled by the paddle even though, of course, each man and bullet move is a separate event. This is a direct consequence of the speed of the program—the time between the bullet move and the paddle-controlled move is so small as to produce the illusion of simultaneity. The game program uses the same principle except here we're drawing a plane after the man draw:

Again, the speed of the program allows us to create the illusion of three shapes moving at the same time. Now, with all this in mind, let's examine the flowchart for the game program.

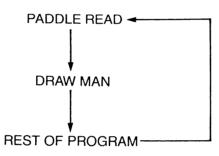

In the program's beginning, we take care of the "housekeeping" chores—the shape addresses are assembled into shape address tables, the screen is cleared and displayed, the bottom line drawn, counters are zeroed, and we initialize the score, man, plane, and bullet. Let's stop here to discuss a point we haven't seen before. Remember that we want to keep track of how many planes are drawn so we can stop the program when 100 planes have appeared (if the perfect score of 100 has not been attained). We do this in the PINITIAL routine because this routine is accessed when, and only when, a new plane is drawn, either after a plane has been hit or when a plane has reached the end of the screen (and of course for the first plane draw). We accomplish this by incrementing PCOUNTER (initially set to zero at the beginning) for each access to PINITIAL and asking whether PCOUNTER contains a value less than 101. If it does, we continue—if it doesn't, we stop the program (we don't do a comparison to 100 because we want the 100th plane to be drawn).

The program then continues with a paddle read and man draw. If there is such a thing as a grand design for a program, we can illustrate it in the following diagram:

Everything else in the program we want to do, drawing the planes and bullets, keeping score, displaying explosions, all the sound effects, reinitializing, are all done in between paddle reads. The program doesn't have to be designed this way—it's just that the program is fast enough so that paddle reads do not have to be done more frequently. The illusion we're striving for (and attaining) is that the man's position is always responsive to the paddle regardless of whatever else is going on. (But note the caveat discussed in Chapter 7—the man's position becomes momentarily unresponsive to the paddle during the explosion shapes display; but note, too, as also discussed in Chapter 7, that this delay is hardly noticeable and could be eliminated by inserting other paddle reads between drawing and erasing the explosion shapes.)

The paddle read routine, you will remember, also contains a "bullet on?" question. If the bullet is not on, BHORIZ is set equal to MHORIZ so that when the bullet is fired, it will be aligned with the man. If the bullet is already on, this step is skipped to allow the bullet to move up independent of the man's position.

After the paddle read, the man is drawn and then we prepare to draw the plane. Here we access the plane shape number a little differently than before for programming convenience. We first increment PSHPNO. Because we want the first shape, PSHPNO should contain #\$00 after we increment. This is why PSHPNO is loaded with #\$FF in PINITIAL—incrementing #\$FF wraps the value around to #\$00. We then ask if the value in PSHPNO is greater than 6; i.e., have we finished all seven shapes? If no, we continue and draw the plane, clicking the

speaker every other cycle. If yes, we move to the next screen byte and ask if we've reached the end of the screen. If no, we load PSHPNO with **#\$**FF again and loop back to INC PSHPNO in preparation for the next plane draw, this time with shape 0 at the next screen byte position. If we have reached the end of the screen, we crase the man (the plane has already been erased by the DRAW-ERASE protocol), and initialize the plane again, thereby also incrementing PCOUNTER. We then test PCOUNTER to see if 100 planes have appeared—if yes, we stop the program; if no, we continue with another paddle read which draws the man, and then the plane is drawn again.

After the plane is drawn, we ask if the bullet is on or if the button is pressed. If neither, we skip the bullet draw routine entirely and erase the man and the plane in preparation for another paddle read—the man's position is updated and the plane moves over one bit. Note a general feature of the program; just before a paddle access, we always erase whatever shape (man, plane, or bullet) that happens to be on the screen, in preparation for the next move.

Supposing the button is pressed or the bullet is already on the screen—we then go to the bullet draw routine before we reaccess the paddle (if the button is pressed, the bullet on marker, BULON, is set). The BDRAW routine first does a collision test before the bullet is drawn. If there is no collision, the bullet is drawn and then the bullet, plane, and man are erased in preparation for the next paddle read. Before we access the paddle however, we move the next bullet position up eight lines and ask if it has reached the top (actually, within five lines of the top). If it hasn't, that's fine—we simply go back for another paddle read. If it has, we have to initialize the bullet first before the paddle read.

Suppose a collision is detected. Here I've changed the protocol slightly to produce what I think is a better display. You remember in Program 8-1 we displayed the explosion first and then the score. This was done so that when the score reached 100 (if all 100 planes were hit) the explosion would finish before the score indicated the program should stop; otherwise, we would be left with an unexploded plane on the screen. I found this delay in displaying the score unnerving—I want to see the score right after that plane is blasted! So here we're going to display the score first, before the explosion.

In the COLLISION routine, we first erase the plane (we always erase the shape that's hit), INC SUM, and then go to SCORE routine. In SCORE, if the count is 100, we print 100 in the display and then, instead of stopping the program, we load an indicator labeled ST with #\$01. If the score is not 100, ST contains #\$00. We then jump back to the COLLISION routine, draw and erase the explosion shapes with the accompanying sound effect, and test ST. If ST contains #\$01, it means the score has reached 100 and we stop the program—remember we've already displayed and erased the explosion so we're not left with an unexploded plane. If ST contains #\$00, the score has not reached 100 and we continue by erasing the man (there's no need to erase the bullet, as the collision test is done before the bullet is drawn), initializing the plane and bullet, and reading the paddle again.

We've now come to the end of the flowchart. A good way to check out a program, to make sure it's doing what we want it to do, is to run through the flowchart considering all possible routes, so let's do that now.

Situation—The man and plane are drawn and the bullet is not fired and is not on the screen.

Flow—After a delay, the man and plane are erased and the paddle read again for another man and plane draw. The plane moves across the screen and the man's movement is controlled by the paddle; nothing else happens.

Situation—The man and plane are drawn but PSHPNO indicates the next plane draw will reach the end of the screen.

Flow—The man is erased and the plane initialized so that the next plane will appear at the starting left border position. If 100 planes have appeared, the program stops; if not, the paddle is read again to update the man's position and the next man and plane are drawn.

Situation—The man and plane are drawn and the button is pressed.

Flow—BULON is set to indicate bullet on and the bullet draw routine is accessed. Because the bullet was not on when the paddle was read, BHORIZ is equal to MHORIZ and the bullet is fired from the man's position.

Situation—The man and plane are drawn and the bullet is on the screen. Flow—BDRAW is accessed but BHORIZ is now independent of MHORIZ, so the bullet can move up independently of the man's position.

Situation—The man and plane are drawn, a bullet is on the screen but not yet at the top, and no collision is detected.

Flow—The bullet is drawn and after a delay, the bullet, man, and plane are erased. The paddle is read again to update the man shape position, the plane moves one bit position and the bullet moves up eight lines. This continues until the bullet has reached the top of the screen or until a plane is hit.

Situation-Same as above but the bullet has reached the top.

Flow—The bullet is initialized, which sets BULON to indicate the bullet is not on and the bullet will not be drawn unless the button is pressed. Thus, we're back to the situation where the man and plane are drawn but the bullet is not on.

Situation—The man and plane are drawn, a bullet is on the screen, and a collision is detected.

Flow—The plane is erased, SUM incremented, the score displayed, and the explosion shapes drawn and erased with the explosion sound effect. If the score is at 100, the program stops. If less than 100, the man is erased, the plane and bullet initialized, and the paddle read in preparation for another cycle.

Situation—A plane has been hit or has reached the end of the screen. Flow—PCOUNTER is incremented for each such occurrence. After 100 such

events, the program stops (unless stopped by the score reaching 100).

This takes us through essentially all the game assembly, as we already know most of the program details. In fact, there is only one minor detail that need be considered. Conditional branch instructions branch to program locations by relative rather than absolute addressing; i.e., the location to be branched to is not specified by a particular address but rather by the distance (in bytes) from the branch instruction. The branching distance is limited, however, by a maximum of 127 bytes forward or 128 bytes back. What do you do if you want to branch to a location outside these limits? Lines 172-174 and 365-368 in Program 10-1 illustrate the solution. In line 172, for example, what we would like to do is

branch to BI with a BLT BI but BI is too far from the branch instruction. So, what we do instead is insert a short branch to a JMP instruction (JMP branches to absolute addresses and thus does not have any distance limitation). The routine is:

```
BLT LONG
....
LONG JMP BI
```

By the way, your assembler will tell you, with an error message, when you attempt to branch beyond the distance limits.

And now—fanfare please—it is with great pride (or at least some pride) and little trepidation that I hereby present THE GAME! (Whoops—it has no name! To enter the Name the Game contest, send \$10 in cash, and also an entry if you like, to me, care of the publisher. The winner will receive a thank you note suitable for framing.)

Well, that's it. Hooray and huzzah. Pop the cork, sound the horn, raise the flag, lean back, light a cigar, and get reacquainted with your loved ones. But don't rest on your laurels too long—there's more to come for all you masochists out there.

In the last chapter, I will make specific suggestions for game modifications using routines discussed in both Part One and Part Two. For now, to get you started and to see how easy it is (and also just for the heck of it), I've decided to present one such modification. The modification is simple—the plane is drawn with the DRAW-DRAW protocol instead of DRAW-ERASE. We can do this because the plane itself is not involved in collision detection, but rather the bullet. Here is the flowchart:

Hi-Res Graphics and Animation Using Assembly Language.....

As you can see, very few changes are required and all relate to the plane erase, which is done with a separate PXDRAW routine using the EOR instruction. In contrast to Program 10-1, where the plane is erased before every paddle access, here the plane is erased at only two places—at the end of the screen and after a collision. You might also notice that the plane sound is a bit higher in pitch with faster clicks—this is because DRAW-DRAW takes less time than DRAW-ERASE.

The change, simple as it is, has resulted in a somewhat better program because the plane moves with less flicker. We'll see in the last chapter how we can effect even other modifications to make the program more interesting.

PART TWO

Advanced Techniques

Drawing in **C**olor

- A computer back named Muller
- Redesigned a dull program for color,
- But his technique was so bad
- The result was quite sad
- For even in color it was duller.

Those of you who have your Apple hooked up to a color TV or monitor, consider yourself fortunate. There is hardly a game program, or any program for that matter, that uses hi-res graphics, that is not enhanced by a color display. In this chapter we'll look first at the mechanics of color production on the Apple and then see how to animate color shapes. We'll also discuss special problems that arise when testing color shapes for collisions. In the last chapter, I'll make some specific suggestions about using color to enhance the game program.

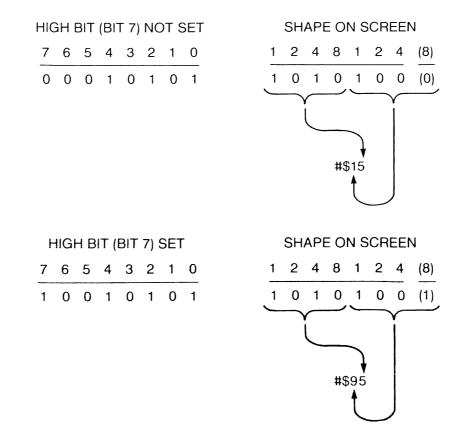

APPLE COLOR

Apple advertises that the hi-res screen can display six colors, but two of these are black and white. Pretty sneaky, eh? There are in fact only four colors available and they are blue, green, violet, and orange. This is not a particular drawback since, as you would see by examining commercial games, quite a lot can be done with just these few colors. For example, one of the most popular Apple games, Flight Simulator II, uses violet for water, blue for sky, green for ground, orange and blue for instruments, and violet for runway lights in nighttime simulation. This works so well that one hardly notices only four colors are used, and this is the rule rather than the exception.

There are two principles involved in hi-res color production. One, if you don't have a color TV or monitor, you won't see color. This point is of such fundamental importance you should make sure you understand it before going any further. Got it? OK. The second principle is that a color shape is produced by plotting in alternate bit positions, that is, in every other column—bits next to each other produce white. In fact, white is produced only by adjacent bits—a single isolated bit is always in one of the four colors. The particular color pro-

duced depends on which columns are used, odd or even, and whether the high bit is set.

Let's discuss these points in some detail. First, the high or most significant bit, which is the left most bit in a byte, is the bit, you will remember, that is not plotted on the screen. Up till now, we've always set the high bit to zero for all our shapes. If the high bit is set to 1, the shape doesn't change, but the shape byte does. For example:

Thus, when the high bit is set, you use it to determine the hex value, remembering that the bit itself does not appear in the shape (actually, if you look carefully on a monochrome monitor, you'll see that dots plotted with a high bit set byte appear about one-half bit position over). This is why #\$80 is equivalent to #\$00 in terms of the shape produced, which in this case is no shape, i.e., black. Similarly, #\$7F and #\$FF will both produce the same white line. Apple refers to these colors as White 1 and White 2 and Black 1 and Black 2 (now we have eight hi-res colors, right?). Ordinarily, one uses black and white with the high bit off to eliminate any problems with detecting collisions with colors that have the high bit set.

As far as odd-even columns are concerned, we use the convention of numbering the first screen bit position at the left of the screen as 0 or the start of the even columns, and the second position as 1 or the start of the odd columns.

The four hi-res colors are produced by the following combinations:

Even columns—high bit not set—violet high bit set—blue

Odd columns—high bit not set—green high bit set—orange

Example

Shape on screen	Higb bit not set	High bit set
1 0 1 0 1 0 1	#\$55 Violet	#\$D5 Blue
0 1 0 1 0 1 0	#\$2A Green	#\$AA Orange

It should be emphasized that the odd-even column assignments always refer to the leftmost screen byte (byte 0). Thus if 1010101 is plotted in screen byte 1, the color will be green or orange, not violet or blue. That's all there is to it, but before we go on to the animation routines, there are two points we must mention. First, because we're plotting shapes as whole bytes, certain color combinations are not allowed. Any contiguous line cannot contain both violet and blue or green and orange because either the high bit is on or it isn't for the particular shape byte. Second, because we're plotting in alternate columns, the 280 dot horizontal resolution of the hi-res screen is reduced by half to 140 dots (the vertical resolution is not affected). This is not as bad as it seems because drawing shapes in different colors often produces an illusion of greater resolution than there really is because of the color contrasts. However, on a black and white monitor or TV, the loss of resolution is readily apparent as color shapes appear to be composed of dotted lines.

COLOR ANIMATION

The major problem in animating color shapes is maintaining the color throughout the screen range (you don't have to do this, but if you don't the result is mighty strange). This is not a problem for vertical animation because the shape bits always maintain their even or odd column assignments. The problem arises, as you might expect, only when dealing with movement that involves a horizontal vector; here, moving a shape in 1-bit moves would result in the bits occupying the wrong columns every other move. Fortunately, the solution to this problem is easy—we simply move the shape 2-bit positions at a time rather than 1; in this way the correct column assignments are always retained. Before we go on to discuss the details, it should be mentioned that 2-bit moves are also often useful for animating non-color shapes if we want, for example, to speed up the animation. The increase in jumpiness that results is generally acceptable. Therefore, the discussion that follows is applicable for both color and black and white animation.

In the next program (Program 11-1) we're going to move a blue plane shape continuously across the screen at the same horizontal line position. The plane shape tables and shape bytes are as follows:

													Blι	Je	Pla	ne																
Shape Numbe	e er	1 :	2 4	4 8	3 1	2	4	1	2	4	8	1	2	4	1	2	4	8	1	2	4	1	2	4	8	1	2	4	SI	nape	Table	<u>}</u>
0							•		•		•		•															_	81 85 D5 D5 D5	80 80 82 8A AA	80 80 80 80 80	80 80 80 80 80

Rive Plane

There are several things that should be noted about these shape tables. Because we want the plane to be blue, the dots are plotted in the even columns only and the shape bytes represent the fact that the high bit is set. Also, note that although the shape itself is 2-screen-bytes wide, the shape table is 4-bytes wide to accommodate all seven shapes. Thus, a general principle—when moving a shape horizontally 2-bit positions at a time, two extra screen bytes in the direction of movement must be included in the shape tables instead of the one extra that we use for 1-bit moves. This necessitates a change in our usual drawing routine. In the MAIN PROGRAM of Program 11-1, when we've finished with all seven shapes, we increment the screen byte by 2 (lines 68 and 69) so that the next draw starts in the appropriate position. We can see this clearly in the shape diagrams above. If shape 0 is drawn in screen byte 0, the next shape 0 must be drawn in screen byte 2 and so on.

That's really all there is. The rest of the program needs no further explanation—we've seen it all before.

--	-------------------------------------	--

Without changing anything in Program 11-1 except the shape bytes, we can draw the plane in any of the other three hi-res colors. Shown on the opposite page are the shapes and shape bytes for shape 0 for the plane in green, violet, and orange.

Shapes with multiple colors can be drawn quite easily, remembering though that a single byte can't contain two colors, one of which requires the high bit set and the other the high bit not set. This precludes a line in a shape within a single screen byte containing both violet and blue or green and orange. The line can, however, contain combinations of violet and green or blue and orange and, of course, different lines in the shape can contain any of the four colors. In addition, black and white can be placed anywhere. Note however that when combining colors, if two bits end up next to each other, white will be displayed in that region. The use of multiple colors, and the contrast they provide, goes a long way in mitigating the lower resolution of color displays.

Simple, yes? But of course for the privilege of drawing in color, there's a price to be paid, and I don't mean the cost of a color TV or monitor (actually, I don't know why this should be so but it seems to be a law of some kind—something about a free lunch?). In any case, we've already discussed one drawback, the lower resolution of color shapes. There is yet another that involves problems in collision detection and we'll get to that next.

COLLISION DETECTION WITH COLOR SHAPES

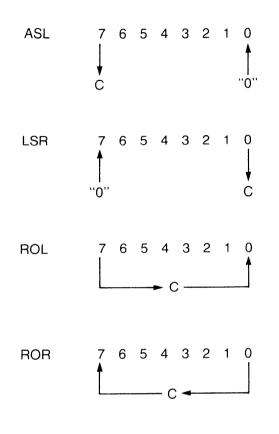

Collision detection with color shapes is difficult for two reasons; first, because such shapes contain "holes," and second, because of a problem relating to the high bit. Let's discuss the "hole" problem first.

Suppose we want to test for the collision of a vertically moving green shape with a violet one:

	76543210	Shape on screen
Shape 1—violet AND with shape 2—green	0101010101 00101010	1 0 1 0 1 0 1 0 1 0 1 0 1 0
Result	000000000	

The AND instruction returns a value of #\$00 indicating no collision, but, of course, a collision should occur. The same situation holds for collisions between violet and orange shapes and between green and blue shapes, because they also occupy different columns. This is not a problem for violet and blue or green and orange shapes because here they occupy the same columns (on the other hand, blue and orange shapes will always indicate a collision, even when there shouldn't be one, because of the high bit problem we'll get to shortly). The same "hole" problem arises with horizontal movement, because color shapes are moved horizontally two bits at a time to maintain the alternate column assignments. We could get around the problem by changing colors, but this would limit our program options and also violate a basic creed of us assembly language programmers, to wit, "#\$FF," or "Flexibility Forever," which translated means if we can overcome a limitation, let's do it.

When dealing with bits in the "wrong" set of alternate columns, the instructions that immediately come to mind are those that shift bits over one position; e.g., ASL (Arithmetic Shift Left), LSR (Logical Shift Right), ROR (ROtate Right), and ROL (ROtate Left).

When we do this kind of shifting, we have to make sure we can restore the original shape and color in preparation for the next shape draw and erase. This is done by storing the shape byte to be tested in the Accumulator, shifting the bits, and then storing the shifted byte into a memory location labeled, let's say, SHIFT (another clever nom de storage). Thus, the shape byte in the shape table is not affected by the shifting. The AND test is then done with the contents of SHIFT and the draw and erase with the shape byte from the shape table.

The instruction we're going to use is LSR because it's the only one that ensures the high bit will contain 0 after the shift—pushing a 1 into the high bit can present problems as we'll see below. Now suppose we want to collision-test a violet with a green shape as in the example in the beginning of this section. Let's see what happens if we LSR the violet shape before ANDing with the green shape:

	76543210
Shape 1—violet LSR AND with shape 2—green	0 1 0 1 0 1 0 1 0 0 1 0 1 0 1 0 1 0 0 1 0 1
Result-non-zero	00101010

Voila! We've detected a collision where there should be one. Let's see how this would look in a program (again, CMP #\$00 is included to make the routine easier to read—it is not needed before a BEQ):

	LDA SHAPE,X	GET SHAPE BYTE TO BE TESTED
	LSR	;SHIFT BITS RIGHT
	STA SHIFT	;STORE IN SHIFT
	LDA (LOW),Y	GET SCREEN BYTE
	AND SHIFT	;AND WITH SHIFT CONTENTS
	CMP #\$00	
	BEQ NOHIT	JUMP TO NOHIT IF NO COLLISION
	JMP COLLISION	
NOHIT	Continue draw with SHAPE,X	

Note that some assemblers require A in the operand column for LSR (and ASL, ROR, and ROL) when the bits in the Accumulator are to be shifted. The exact same procedure can be used for testing violet against orange and green against blue. When we get to blue vs. orange, however, we have a problem, because both colors have the high bit set and thus an AND test will always return a non-zero even when no collision is indicated. This occurs because both high bits are 1. Consider the following:

	76543210	Shape on screen
Shape 1—orange AND with shape 2—blue	$\begin{array}{cccccccccccccccccccccccccccccccccccc$	$\begin{smallmatrix} & 0 & 1 & 0 & 1 & 0 & 0 & 0 \\ & 0 & 0 & 0 & 0 & 0 & 0 &$
Result-non-zero	10000000	

Obviously a collision should not be detected, but it is because of the high bits. We might assume an LSR instruction would take care of this, because it places a zero in the high bit; but watch what happens:

	76543210
Shape 1—orange LSR AND with shape 2—blue	1 0 0 0 1 0 1 0 0 1 0 0 0 1 0 1 1 1 0 0 0 0
Result-non-zero	0100000

The high bit has been shifted into the shape byte and, in this case at least, an erroneous collision detection has occurred. What we want to do then is mask out the high bit before shifting. We do this by ANDing with #\$7F. Thus:

	76543210
Shape 1—orange AND with #\$7F	1 0 0 0 1 0 1 0 0 1 1 1 1 1 1 1
Result—high bit 0 LSR AND with shape 2—blue	$\begin{array}{cccccccccccccccccccccccccccccccccccc$
Result-zero	000000000

In a program, the routine would look like this:

LDA SHAPE,X AND #\$7F LSR STA SHIFT LDA (LOW),Y AND SHIFT CMP #\$00 BEQ NOHIT etc.

Even when testing blue or orange against a high-bit-not-set color, such as violet or green, it's still a good idea to mask out the high bit so that it doesn't get pushed into the shape byte. To summarize then:

Color to be tested (ANDed)	Target color	Shift instructions
violet green blue orange green violet blue orange white (high bit off)	blue orange violet green violet or blue green or orange green or orange violet or blue any color	none none none LSR LSR AND #\$7F, LSR AND #\$7F, LSR none
any color	white (high bit off)	none

This is a fast and simple procedure, but not without its drawbacks. Because we're shifting the shape bits, in certain circumstances a collision detection will result when the shapes are not exactly at the collision site. For shapes moving vertically, this displacement will not exceed one bit position and this should certainly be tolerable in most circumstances. For shapes moving horizontally, the displacement can be as large as three bit positions, because the protocol is draw-erase-move two bit positions-LSR-AND test. We can reduce the displacement to one bit position by altering the protocol to the following; move two bit positions-draw-LSR-AND test-erase. But as mentioned, this displaced collision is not a problem in all cases—it depends on the shapes and which way they're moving.

A second method of collision detection with color shapes is one that seems to be favored by assembly language programmers, probably because the principle is simple and it works; there is also no problem with displaced collisions. The method involves setting up a second dummy shape table, identical to the first, except that the shape is drawn in white (high bit off), i.e., no "holes." The white shape is ANDed with the screen byte, and the color shape is used to draw and erase. For example, if the color shape is stored in COLOR and the white shape in WHITE, the routine would be as follows:

LDA (LOW),Y AND WHITE,X CMP #\$00 BEQ NOHIT JMP COLLISION NOHIT Continue draw with COLOR,X

This method works for any color combination and eliminates the problem of the high bit. An obvious drawback, however, is that multiple shape tables have to be constructed for each shape involved in collision detection. This can eat up a lot of space for programs with many colliding shapes, not to mention the time involved in writing the program. There can also be a significant increase in execution time, depending on the type of animation involved. For vertical animation, this is not a significant problem—a single shape would have only two shape tables, one in color and the other in white, and the routine described above can be used without any modification. For horizontal movement, however, each shape would require 14 shape tables instead of 7, and if we use our usual TEMP loading routine, we would have to load another TEMP with the white shapes for each AND test. This could increase the execution time to intolerable levels and if so, we would then have to use routines that do not involve TEMP loading; that is, a separate draw routine for each shape as discussed in Chapter 5 (Program 5-2). This would further increase our program size, but then you can't have everything.

There is yet a third method we can use, which is both simple and fast, but has the limitation that the shape has to be all one color. What we do is use a single white shape table and then mask the shape to color. For example:

	76543210
White shape AND with #\$55	00011100 01010101
Result—violet shape (even columns)	00010100

A program using this routine would look like this:

LDA (LOW),Y AND WHITE SHAPE CMP #\$00 BEQ NOHIT JMP COLLISION NOHIT LDA WHITE SHAPE AND #\$55 STA COLOR SHAPE LDA (LOW),Y EOR COLOR SHAPE For a green shape, we would AND with #\$2A, for orange with #\$AA, and for blue with #\$D5. This routine requires only one (white) shape table, but obviously can be used only with shapes of a single color, because each color requires a different value to be ANDed. The only exception would be if we are testing a vertically moving shape and expect no side collision. Here, only the top or bottom line (white shape) need be collision-tested and then, if no collision, the whole color shape can be drawn with a separate routine.

Which to use, LSR or white dummy shapes? That depends on the program and your own proclivities. Use whichever is easier and more appropriate. On the other hand, we could observe another assembly language credo, "#\$EB," or "Easy is Better"—just change the shape colors to those that don't involve alternate columns.

Finally, let's discuss the game program for a moment. Suppose we draw the plane in blue. The bullet is a single dot and thus is either violet or green depending on the column in which it is drawn. Thus, half the time a collision will be missed, i.e., when the bullet is tested against a "hole" in the plane shape. Note that this is a special situation—ordinarily shapes are not just single dots. What to do? An LSR would be inappropriate—we would still miss collisions the other half of the time and if the shape byte were #\$01, an LSR would empty the shape byte entirely. We could use a white dummy table—here the bullet would be 2-bits wide—but instead of going through all that trouble, why not just draw the bullet as a 2-bit wide white shape to begin with? Why not indeed. It works and looks fine—what more could we ask for?

Double **H**i-**R**es **G**raphics and Animation

- A computer artist from Labore
- Has only one problem; he can't draw.

Hi-res double

- Gives him nothing but trouble,
- Now he's twice as bad as before.

A hose of you with Apple IIc's or extended memory Apple IIe's have probably sat up many a night wondering what to do with the extra memory these machines contain. You can't use it for your BASIC programs (it can be done but Apple won't tell you how) and only some commercial programs take advantage of it. But we're assembly language programmers and no part of Apple memory is inaccessible to us. In this chapter, we'll see how to use the extra memory to display and animate graphics in the double hi-res mode, both in color and black and white.

DOUBLE HI-RES—WHAT IT IS AND WHAT'S REQUIRED

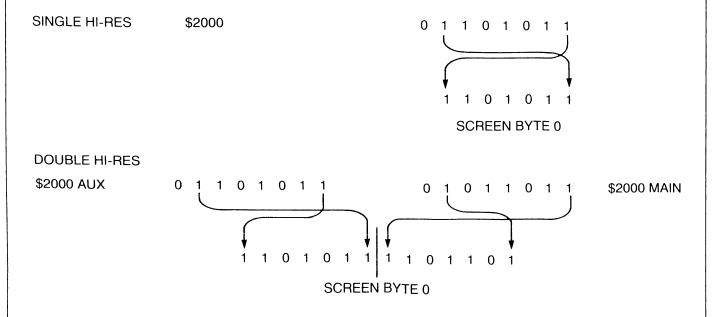

Not all Apples are capable of displaying double hi-res graphics—at the very least a minimum of 128K of memory is required. Apple IIc's come with 128K standard. Apple IIe's can be upgraded to 128K by adding an extended memory 80-column card (available from Apple and other companies) but double hi-res graphics also require that you have a revision B or later motherboard. You can tell what revision your motherboard is by checking the part number at the rear of the main circuit board. If the letter following the numbers is B, you're all set. If it is A, you have a revision A motherboard and double hi-res will not work. But don't despair—your Apple dealer will sell you a B motherboard at a price you can't refuse; all you have to do is learn how to program with one hand.

Another requirement, but one that is not absolutely essential, is a video monitor rather than a TV. You can use a black and white or color TV, but much detail will be lost, thus negating the increase in resolution and the details of color contrasts. You don't have to spend a lot of money for fancy monitors—I find the standard Apple monochrome monitor superb for double hi-res displays and even an inexpensive color monitor produces satisfactory results.

Double hi-res extends the horizontal resolution of the hi-res screen from 280 to 560 dots on a monochrome monitor—the vertical resolution remains the same at 192 lines. The 560 by 192 screen makes the Apple with double hi-res roughly equivalent to the hi-res mode on the IBM PC (600 by 200) and, as you might imagine, this increase in resolution can produce startlingly detailed graphics that make single hi-res appear rather crude. With color, the horizontal resolution is the same as single hi-res (140 dots), but with many more colors available and without the single hi-res color mixture limitations.

THE DOUBLE HI-RES SCREEN

The extra 64K of memory in 128K machines is essentially a mirror of the standard 64K memory block; that is, there are two of everything, including the hi-res screens. Let's label a hi-res screen from the standard memory as MAIN and the screen from the extra memory as AUX, for auxiliary. Each screen uses the same addresses; i.e., \$2000 is the first screen byte position for hi-res Page 1 for both MAIN and AUX. For this reason, you have to specify which memory you're using before sending shape bytes to a hi-res screen location. Now remember that in single hi-res, 7 bits from a shape byte are plotted in a single screen byte. Thus, a shape byte sent to \$2000 will be displayed in the first screen byte of hi-res Page 1. In double hi-res, each screen byte displays 7 bits from a shape byte from AUX and 7 bits from a shape byte from MAIN, the shape from AUX displayed in the first half of the screen byte. Thus, a shape byte sent to \$2000 in AUX will be displayed in the first screen byte 0) and a shape byte sent to \$2000 in MAIN will be displayed in the second half (assuming, of course, that the double hi-res mode is selected).

Similarly, a shape byte sent to \$2001 in AUX will be displayed in the first half of screen byte 1, and a shape byte sent to \$2001 in MAIN will be displayed in the second half of screen byte 1, and so on. There are still just 40 screen bytes, but each can display up to 14 dots, which accounts for the 560 dot resolution ($14 \times 40 = 560$). All that needs to be done is to specify AUX or MAIN before sending the shape byte to the particular hi-res screen address—the double hi-res mode

takes care of the plotting. Note that, as in single hi-res, the high bit does not appear in the shape. Not only that, but in double hi-res the high bit has nothing to do with color selection as we'll see in a later section.

THE DOUBLE HI-RES MODE

Strange as it may seem, you cannot draw in double hi-res unless you first set the double hi-res mode. The way to do this is buried deep within the Apple reference manual and if you're fond of frustration, you're welcome to try to dig it out, but why not just read on? The method, as you might suspect, involves accessing certain soft switches, some of which you've seen before.

Label	Address	Access	Function
GRAPHICS MIXOFF HIRES AN3 COL80 STORE80 AUX MAIN	\$C050 \$C052 \$C057 \$C05E \$C00D \$C001 \$C055 \$C054	LDA LDA LDA STA STA LDA LDA	Turns on graphics mode Selects full page graphics Selects hi-res mode Turns off annunciator 3 Selects 80 column mode Changes functions of next switches Selects AUX when STORE80 and HIRES on Selects MAIN

The routine for selecting double hi-res is as follows:

LDA GRAPHICS LDA MIXOFF LDA HIRES STA STORE80 STA COL80 LDA AN3

Once this is done, LDA AUX selects the Page 1 hi-res screen from the auxiliary memory and LDA MAIN selects the same page from main memory. Thus, to clear both screens, we do:

LDA MAIN JSR CLEAR LDA AUX JSR CLEAR

where CLEAR is our usual clear screen subroutine. It's simple when you know which switch to pull (push?), thus attesting to the old adage (which I just thought of) that computers imitate life.

DRAWING SHAPES

Drawing a shape on the double hi-res screen is relatively easy—all we have to do is determine in which half of the screen byte, AUX or MAIN, the shape bits are to be plotted and modify the draw routine accordingly. For example, let's look at how we would plot some simple shapes of varying lengths. To keep it really simple, we'll just plot some lines. For most of the programs in this chapter we'll be using single lines to illustrate the principles involved; however, the programs are designed in the usual way (i.e., XCOUNT, DEPTH, etc.) to allow the drawing of shapes with multiple lines, so our examples are applicable not just to lines, but to any shape.

 Screen byte 12

 AUX
 MAIN

 0 1 1 1 0 0
 0 0 0 0 0 0 0

Here we're plotting shape byte #\$1E just in the AUX portion of the screen byte. The draw routine would look like this (we're using the EOR method for illustration):

LDA AUX LDA Screen byte EOR #\$1E STA Screen byte

Suppose now we want to draw a line extending into the MAIN section:

Screen byte 12 AUX | MAIN 0 0 0 0 1 1 1 | 1 1 0 0 0 0

The draw routine would then be:

LDA AUX LDA Screen byte EOR #\$70 STA Screen byte LDA MAIN LDA Screen byte ;SAME SCREEN BYTE EOR #\$07 STA Screen byte

Now let's extend a line into the next screen byte:

Screen	Screen byte 13	
	MAIN 1 1 1 1 1 1 1	

The draw routine would be:

LDA AUX LDA Screen byte EOR #\$70 STA Screen byte LDA MAIN LDA Screen byte EOR #\$7F STA Screen byte INY ;NEXT SCREEN BYTE LDA AUX LDA Screen byte EOR #\$03 STA Screen byte

Note that we use INY to get to the next screen byte, because this is how we have always done it in our programs: Y is loaded with the value in BYTE and it is manipulated to access different screen bytes within the draw routine instead of BYTE itself to make erasing easier.

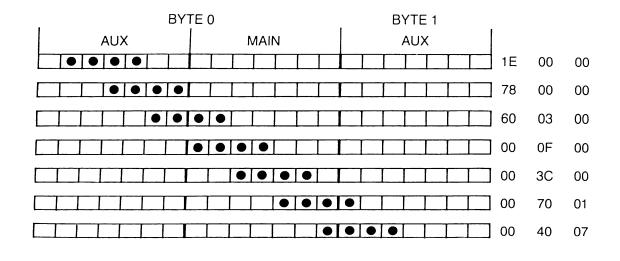

We can use a kind of shorthand to describe our double hi-res drawing routines. Thus, for the example above, A-M-INY-A. The same line starting in the MAIN section would use M-INY-A-M. A line extending over two whole screen bytes and starting in AUX would use A-M-INY-A-M, and so on. For a shape with multiple lines, we simply plot out the shape and design the draw routine based on the overall maximum shape width.

Now that we know how to display shapes on the double hi-res screen, let's see how to animate them.

ANIMATING SHAPES

Vertical animation, as usual, presents no problems. We just draw and erase the shape and change line positions; the shape bits always retain their column assignments. Non-vertical movement always contains a horizontal vector, and here things get more complicated, but not much more than with single hi-res horizontal movement. First of all, for greater simplicity, all our double hi-res horizontal animation will use 2-bit moves. One-bit moves are possible but involve greater complexity (14 shapes are required with different draw routines for each group of 7), and they are completely unnecessary because a 2-bit move in double hi-res is equivalent to a 1-bit move in single hi-res and this is certainly satisfactory.

With 2-bit moves, we need only 7 shapes. The technique is to examine the shape tables and devise the appropriate draw routine. Most everything else is the same as in our previous single hi-res programs. Let's consider the simplest example, a line occupying only half a screen byte and starting in the AUX section. Shown below are the shape tables for this line moving in 2-bit moves. (Note that as usual with 2-bit moves, 2 extra bytes have to be included in the shape tables in the direction of movement, but here the extra bytes are really half screen bytes, i.e., either a MAIN or AUX.)

Examination of the tables tells us the draw routine needed is A-M-INY-A. The tables also tell us that after seven shapes are drawn, we start over with the first shape in AUX in the next screen byte, and so we do an INC BYTE. This is in contrast to 2-bit moves in single hi-res where we have to move 2 bytes over after every seven shapes. Thus the protocol can be represented by A-M-INY-A—next screen byte—A-M-INY-A.

Let's now use these shapes in a program. The following program (Program 12-1) moves the line left to right across the screen in the same way that we moved the plane shape in previous programs. There is very little change from a single hi-res program, the major alteration being in the draw routine. The flow-chart for Program 12-1 is on page 235.

...... Double Hi-Res Graphics and Animation

The program can be modified easily to move lines of any length by altering the draw routine. For a line occupying both AUX and MAIN of one screen byte, the protocol is A-M-INY-A-M—next screen byte—A-M-INY-A-M. For a line occupying AUX and MAIN of one screen byte and AUX of the next, we would use A-M-INY-A-M-INY-A—next screen byte—A-M-INY-A.M-INY-A, and so on.

To demonstrate how to draw complicated shapes, I've included the following program, which moves a spaceship vertically. Running this program will illustrate how neat double hi-res is compared to single hi-res.

---	--	---	--	---	---	--

We've seen that drawing and animating shapes in double hi-res is relatively simple—just by examining the shape tables we can tell what kind of draw routine is required. The only difficulty is that the extra resolution afforded puts greater demands on our artistic talents, whatever they may be. But with this greater demand comes a greater opportunity and the extra work required is well worth the results.

DOUBLE HI-RES COLOR SHAPES

Displaying color in double hi-res requires quite a different procedure from single hi-res. First, the high bit has nothing to do with color selection-it is simply ignored. Second, colors are not produced by plotting dots in alternate rows, but rather are determined by the particular combination of 4 dots or bits displayed at particular positions on the screen. For example, if we were to place 0 0 0 1 in AUX1, the first screen position at the left of the screen, magenta would be displayed. If instead we plotted 0 1 0 0, we would get a dark green, 0 1 1 1 a yellow, and so on. As there are 16 combinations of 4 bits, 16 colors are available. However, one is white, one is black, and there are two greys, and so actually we have 13 colors to choose from, quite an improvement over the 4 colors in single hi-res. Because the horizontal resolution in double hi-res is 560 dots and we use 4 for each color, the resolution in double hi-res color is 560/4 =140 or the same as in single hi-res color. But, with more colors to choose from, we can display more interesting graphics and with more apparent resolution because of color contrasts. Also, as we'll see, there is no limitation to color combinations within lines as there is in single hi-res.

Because the high bit of the shape byte is not plotted, this presents a problem when we want to repeat a particular dot pattern on the screen, which we would do, for example, in plotting a line of a single color. Suppose we want to display a dark blue line. The repeated dot pattern we want on the screen is 1 0 0 0. If we plot shape byte #\$11 in AUX1, we will get the desired pattern, but if #\$11 is also plotted in the next byte, MAIN1, see what happens:

Obviously, the desired pattern is not repeated. The pattern is repeated, however, by plotting #\$22 in MAIN1 and to continue the pattern, we would plot #\$44 in AUX2 and #\$08 (or #\$88) in MAIN2, the next two positions over.

AUX1	MAIN1	AUX2	MAIN2
#\$11	#\$22	#\$44	#\$08
1000100	0100010	0010001	0001000

After these 4 bytes, the pattern repeats itself, starting with #\$11 in AUX3, #\$22 in MAIN3, etc. If we were to plot a dark blue line from AUX2, for example, the bytes would be #\$44, #\$08, #\$11, #\$22, #\$44, etc. Thus, each color has its own sequence of 4 bytes, the particular starting byte required depending on the distance from the left screen border. The dot pattern and the 4-byte sequence for each of the 16 colors is shown in Table 12-1.

<i>Table 12-1</i>							
Color	Bit Pattern	AUX1	MAIN1	AUX2	MAIN2		
Black Magenta Brown Orange Dark Green Grey 1 Green Yellow Dark Blue Violet Grey 2 Pink Medium Blue Light Blue	$\begin{array}{cccccccccccccccccccccccccccccccccccc$	#\$00 #\$08 #\$44 #\$22 #\$2A #\$66 #\$11 #\$19 #\$55 #\$5D #\$33 #\$3B	#\$00 #\$11 #\$08 #\$19 #\$44 #\$55 #\$4C #\$5D #\$22 #\$33 #\$2A #\$3B #\$66 #\$77	#\$00 #\$22 #\$11 #\$33 #\$08 #\$2A #\$19 #\$3B #\$44 #\$66 #\$55 #\$77 #\$6E	#\$00 #\$44 #\$22 #\$66 #\$55 #\$53 #\$77 #\$08 #\$4C #\$6E #\$19 #\$5D		
Aqua White	1 1 1 0 1 1 1 1 1 1 1 1	#\$3B #\$77 #\$7F	#\$77 #\$6E #\$7F	#\$5D #\$7F	#\$3B #\$7F		

This table is useful for drawing any color line anywhere on the screen. The particular starting point determines which byte is used first, then the other bytes are plotted in sequence. This is fine for a line of a single color but what if we want to plot a line with two or more colors? If the new color starts at a 4-byte boundary, we continue with the next sequence of 4 bytes for the new color. Thus, to plot a line in dark blue and magenta, with each color containing 4 bytes, the sequence would be 11,22,44,08,08,11,22,44. If the new color starts in the middle of a 4-byte sequence, we have to calculate a new byte at the color shift point by inspection. Let's say we want to plot a line containing 2 bytes of dark blue and 2 bytes of magenta. From Table 12-1 we get the values 11 and 22 for the dark blue in AUX1 and MAIN1, and 22 and 44 for the magenta in AUX2 and MAIN2. See what happens when we plot these bytes:

AUX	1	MAIN1	I	AUX2		MAIN2	
#\$11		#\$22		#\$22		#\$44	
10001	00	01000	10	01000	10	001000	1
L	L		L			J L	L
blue	blue	blue	viole	et magen	ita ma	agenta magent	a

Obviously, a different byte is required to turn that fourth position into either blue or magenta. Let's change it to a dark blue. The byte to be plotted in AUX2 is #\$20:

AUX1	MAIN1	AUX2	MAIN2
#\$11	#\$22	#\$20	#\$44
1000100	0100010	0000010	0010001
blue blue	blue blu	ue magenta ma	igenta magenta

Similarly, if we want to change the fourth position to magenta, the order of bytes would be 11, 02, 22, 44. I wish I could think of some formula to make this kind of change easier but I can't—I think it just has to be done by inspection, but this is not so bad. You just decide what colors you want, inspect the dot patterns, and choose the bytes accordingly.

Note that there is no limitation for color combinations within a line—any of the 16 colors can be placed next to any other. This provides for much greater flexibility than is available in single hi-res color, over and above the larger number of colors available.

Drawing a shape in double hi-res color takes some getting used to. What you have to do is imagine that every 4 bits plot a single dot, so there are seven possible dot plots for every two screen bytes, just as in single hi-res color. The shape is plotted out, the shape bytes assembled into the usual shape tables, and the shape can then be drawn with the double hi-res routines described in the beginning of this chapter. We'll see an example in the next section.

I say "imagine" every 4 bits plot a single dot because in actuality, each bit that's "on" in the set of 4 is plotted. This is most easily seen on a monochrome monitor, but it does have implications for the color display as well. To see what this is all about, run the following program, which displays all 16 colors as lines, each directly below the other, and observe the display on both a color and monochrome monitor.

---	---	---	--	--	---	-------------------------------------	---

On a monochrome monitor, preferably with the aid of a magnifying glass, you would observe the following dot patterns, but of course much closer than shown:

Magenta	0001	•	•	•	•
Brown	0010	•	•	•	•
Orange	0011	••	••		••
Dark Blue	1000	•	•	•	
Aqua	1110		• • •		• • •

This is why double hi-res colors are distinguishable on a monochrome monitor—they all have a different dot pattern. On a color monitor, at least on mine, the individual dots are not seen; continuous color lines are.

There is a problem, however, in the color display. Look at the color monitor. Although each line is plotted starting from the first screen position (AUX1), not all line up exactly. The most extreme example is magenta and dark blue as you might suspect, because the dot patterns are 0001 and 1000; i.e., the "on" bits are at opposite ends of the 4-bit group. Other color combinations also have this alignment problem to a degree depending on the particular dot patterns—the closer the "on" bits are to each other, the lesser the problem. Thus, the 4-bit pattern not only selects a particular color, but also changes slightly exactly where the color is drawn. This presents the only limitation I can think of regarding double hi-res color combinations. If you want lines to align themselves closely, there are certain color combinations that should not be used. Thankfully, most combinations result in only a minor misalignment, so this is not a big problem but is one you should be aware of when designing your shapes.

ANIMATING DOUBLE HI-RES COLOR SHAPES

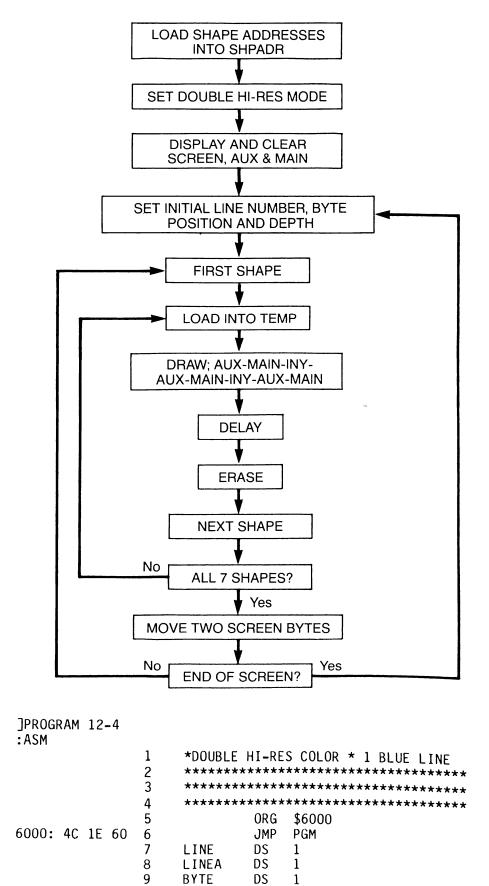

Is there a problem with vertical animation? Boo and hiss to those who answer yes. As there is no change in column assignments, the shape is just drawn once and moved up or down by changing screen line positions. Is there a problem with horizontal animation? Does Apple make computers?

Let's consider a program (Program 12-4) that moves a single dark blue line across the screen. The line length is just 2 bytes, so the first shape, at the left screen border, contains bytes #\$11 and #\$22 from Table 12-1. The line could be moved in whole screen-byte intervals, but this makes for rather jerky movement, so we'll use half screen-byte jumps. As with other types of horizontal movement, here too we use seven shape tables, but the particular bytes required cannot be taken from Table 12-1 except for the first shape. To illustrate this, let's look at the seven shape tables and see what bytes are required to obtain the desired dot pattern.

Shape 1	AUX1 MAIN1 AUX2 MAIN2 AUX3 MAIN3 #\$11 #\$22 #\$00 #\$00 #\$00 #\$00 10001000100000000000000000000000000
Shape 2	#\$10
Shape 3	#\$00 #\$22 #\$44 #\$00 #\$00 #\$00 00000000010001000100010000000000000
Shape 4	#\$00 #\$20 #\$44 #\$08 #\$00 #\$00 0000000 000010 0010001 0001000 0000000 000000
Shape 5	#\$00 #\$00 #\$44 #\$08 #\$01 #\$00 0000000 000000 0010001 0001000 1000000 000000
Shape 6	#\$00 #\$00 #\$40 #\$08 #\$11 #\$00 0000000000000000000000000000000000
Shape 7	#\$00 #\$00 #\$08 #\$11 #\$02 0000000 000000 000000 0001000 1000100 0100000

Once the seven shapes are drawn, the pattern is repeated, but with the first shape now drawn 2 screen bytes over, i.e., #\$11 in AUX3 and #\$22 in MAIN3, etc. Thus, in the MAIN PROGRAM, we do INC BYTE twice after each seven shapes. Each shape table consists of 6 bytes and the draw routine is A-M-INY-A-M-INY-A-M-2 bytes over—A-M-INY-A-M.INY-A-M, etc. The remainder of the program needs no further explanation, except to remind you that it can easily be adapted to multiple line shapes by extending the shape tables and modifying TEMP and the load shape routine accordingly. Thus, to draw two blue lines of the same length, one under the other, the shape 1 table would be 11, 22, 00, 00, 00, 00, TEMP would be changed to DS 12, and in the

This is a simple program, but it illustrates the basic principles of horizontal animation in double hi-res color. For more complicated shapes with multiple colors, all one has to do is map out the shape to get the proper shape bytes and to design the proper draw routine. To see double hi-res color in action, run the following program, which moves a wildly colored spaceship vertically (I don't have an extra month to draw the seven shapes for horizontal movement).

Curved and **D**iagonal **M**ovement

Moving up and down and to and fro Is easy enough as you well know, But moving at an angle Can cause quite a tangle

As you change each column and row.

Up until now we've only considered shapes moving either vertically or horizontally, but sometime in your career as a graphics computer programmer you might want to display other types of movements without having to tilt or rotate the monitor. The principle is easy. For vertical movement, we keep the screen byte constant and alter the line position; for horizontal movement, the line position is kept constant while the screen byte is changed (stop me if I'm going too fast). For diagonal or curved movement we change both the screen byte and line position for each draw. I told you it was easy.

Armed with this information we can now move shapes around in any kind of meandering path but, in general, pleasant results are obtained only if shapes move in some kind of recognizable pattern, either diagonally or in a curve described by some type of simple equation (don't worry, we're not going to get into quantum mechanics or even calculus, but keep in mind that $E = mc^2$). An exception to this is when movement in all directions is controlled by a joystick or paddles as we saw in Chapter 6 (Program 6-3).

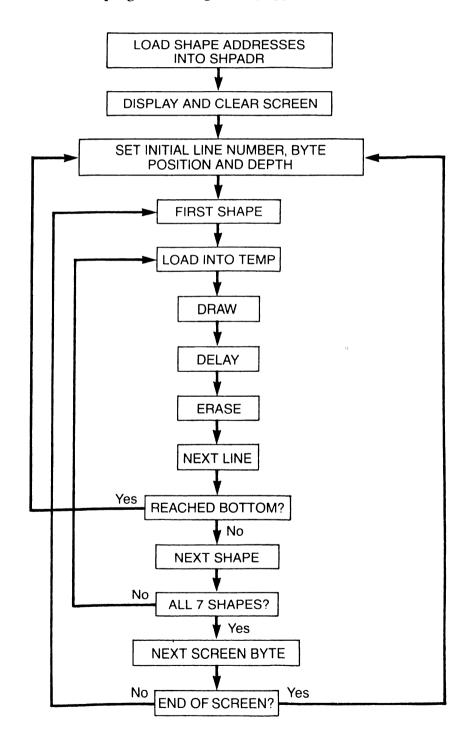

DIAGONAL MOVEMENT

For any kind of non-vertical movement, there is always a horizontal vector and so we have to use the horizontal protocol, i.e., seven preshifted shapes. To illustrate diagonal movement, we're going to use Program 5-1 as a starting point—it moves a plane shape across the screen.

For our first example, let's move the plane down one line for each horizontal 1 bit move (see Program 13-1). After each draw and erase, we do an INC LINEA (remember, we don't INC LINE because LINE is altered in the draw routine). Before going on, we test to see if we've reached the bottom of the screen (line

..... Curved and Diagonal Movement

#\$BA). If we have, we start over. If not, we continue by loading LINE with LINEA, adding the shape depth to LINE, and storing in DEPTH (DEPTH has to be changed each time the line position is changed). We then continue with the usual routine, i.e., next shape number, etc., and also test for the end of the screen. In this particular example, the plane will reach the bottom first before reaching the end of the screen because there are only 192 lines but 280 horizontal bit positions. However, we're testing for both bottom and end of screen to make the program more generally applicable.

We can make the plane drop at an even steeper angle simply by increasing the line positions more often than once every horizontal move. We would do INC LINEA twice, or three times, or however many we want before going on to the next draw, but keep in mind that we want to keep the line jumps to a reasonably small number to maintain smooth animation. We could, with a more complicated protocol, draw the shape at each line position instead of after each every two or three line moves, but this results in a rather noticeable jerky motion. Line jumps between draws result in a more acceptable animation as long as the distance between draws is kept small (large jumps are okay for fast moving shapes, as we'll see below).

Suppose now we want the plane to drop at a shallower angle, let's say one line for every two horizontal moves. The next program (13-2) illustrates how this is done. We set up a counter labeled DE and set it to zero in the INITIAL subroutine. After the first draw and erase, DE is incremented by 1. If DE is less than 2 (line 67), we continue drawing on the same line. After the shape has been drawn and erased two times, DE = 2 and the branch at line 68 is not taken; DE is zeroed, LINEA is incremented and, if the bottom has not yet been reached, drawing continues, now one line down. Note that each time LINEA is changed, LINE is loaded with LINEA and DEPTH is adjusted (line 76). We can easily make the shape fall in a shallower angle by changing the CMP value in line 67. Thus, if we do a CMP #\$03, the shape will move three horizontal positions between each line change.

CURVED MOVEMENT

In general, when moving shapes that are meant to represent some object in the real world, such as planes, bullets, bombs, or what have you, realism is effected only when the path represents how such shapes actually move. This usually means the path must follow some sort of defined curve such as a circle, parabola, etc. Of course, if you're moving a shape that looks like a snigglehof, you can twist it around any way you want, but the example I'm going to use is falling bombs, not only because it fits in well with the game program, but also because it expresses my militaristic aggression (you'll get this way, too, after a few bouts with assembly language programming).

Actually, the falling bomb example is applicable to any falling object. When something falls as a result of the force of gravity, it is constantly accelerating; that is, its vertical drop per constant horizontal displacement continually increases until it hits something or is slowed by air resistance. Let's put this in the form of equations to see how it works. We calculate new line positions as follows:

> VX = VX + 1LINE = LINE + VX

The following table illustrates how line positions change for each constant horizontal move.

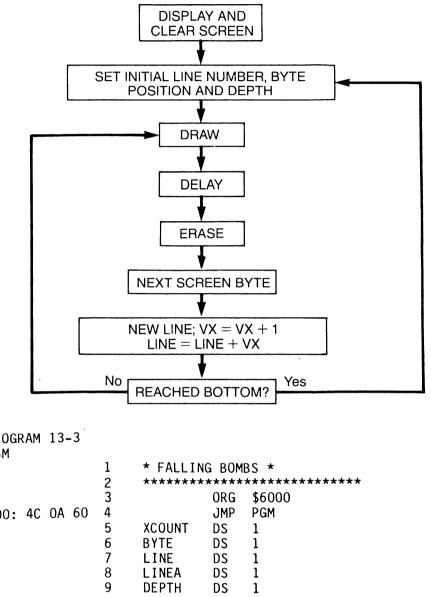

Horizontal Position	Line	VX	New Line
0	0	0	0
1	0	1	1
2	1	2	3
3	3	3	6
4	6	4	10
5	10	5	15
6	15	6	21

Obviously what's happening is that the distance between lines is constantly increasing by a value equal to VX and the resulting path describes a falling object exactly. Now let's see how we can put this to work in a program.

First of all, I've decided to draw the bomb at each new line position rather than continuously at each screen line; i.e., the bomb is drawn only after each line jump regardless of the distance involved. What this means is that as the bomb approaches the bottom of the screen, there will be rather large line intervals between draws, but this is just what we want. The bomb should be moving faster as it approaches the bottom and the larger line jumps provide just this illusion. Large jumps are appropriate for fast moving shapes. Look at the bullet moves in the game program—here, too, the shape is moving 1 byte (eight lines) at a time. Note also that if the bomb were drawn at every line position and not just at the new lines, the large jumps from new line to new line would be eliminated, but the result would be jerky animation and the illusion of increasing speed would be destroyed—the bomb would appear to be moving at a constant (jerky) speed all the way down. The only way to increase the apparent velocity in this case would be to shorten the delay times as the bomb falls, a tricky and unnecessary exercise, and one that wouldn't eliminate the jerky animation anyway.

The horizontal displacement of the bomb as it falls can vary from 1 bit to 1 byte or any other value you want. The displacement will not affect the acceleration illusion (this depends on the line changes), but only the steepness or shallowness of the fall. I've chosen a 1-byte move because it looks right. A 1-byte horizontal move also simplifies the program considerably because we need only one shape and not seven. The same shape is plotted at each new screen byte position. For shorter moves, we would have to use the seven preshifted shapes and change line positions after testing SHPNO for the desired values.

In the MAIN PROGRAM of Program 13-3, we draw and erase, INC BYTE, add 1 to VX, then add the value in LINE to VX and store the result in LINE and LINEA. We adjust DEPTH for the new line, test for the bottom of the screen, and then continue drawing.

In this program, once the bomb has reached the bottom, we start over, but we can insert any other routine here, such as an explosion, decrement score, etc. If we want an explosion—for example, when the bomb reaches the screen bottom—we need only test for the bottom line of the screen and jump to an explosion routine. If we want to test for the bomb hitting the man in the game program, we would have to include a collision test for the bomb itself, being careful to calculate just which line or group of lines the bomb would reach when hitting the man. To distinguish between hitting bottom or hitting the man, we need only determine at which line the collision occurred, as the bottom line and the man occupy different line positions.

Finally, one can add more realism to falling shapes by simulating the effect of air resistance. At some point in an object's fall, air resistance will cause the acceleration to cease and the object will fall at a constant speed. We can effect this simulation by not allowing VX to go above a certain value—when VX remains constant, the line intervals will then also be constant. A routine to accomplish this would be:

	LDA	VX
	CMP	#\$04
	BGE	CONT
	CLC	
	ADC	#\$01
	STA	VX
CONT	CLC	
	ADC	LINE
	etc.	

Drawing over Backgrounds

- A computer artist named Pound
- Drew a woman shape nicely round.
- Her repute was not well,
- And just so you could tell,
- He used an unsavory background.

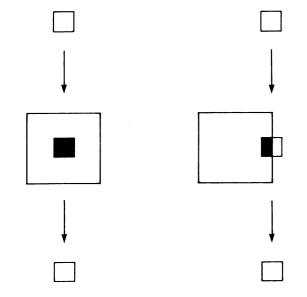

D ackgrounds can enhance any program displaying hi-res graphics, not only game programs. A background can consist of stationary shapes (clouds or stars for a sky scene, for example) or moving shapes where collisions are not desired (shapes passing in the night?). Drawing a shape behind or in front of another shape can create the illusion of depth. In addition, one can use the whole screen as a background. For example, if we load the Accumulator with #\$7F instead of #\$00 in the clear screen routine, we can draw black shapes on a white background. Similarly, we can produce whole screen color backgrounds with the clear screen routine by LDAing with the appropriate bytes; #\$55 in the even columns and #\$2A in the odd columns will produce a violet screen, and so on.

WHITE SHAPES AND BACKGROUNDS

The trick to drawing over backgrounds is to have the object and the background retain their original shapes following draw-erase cycles. The easiest way to do this is to use EOR for both drawing and erasing, i.e., the usual DRAW-ERASE protocol. Let's see what happens when we EOR a shape with a background:

$\begin{array}{c}1 & 1 & 1 & 1 & 1 & 1 & 1 \\0 & 0 & 1 & 1 & 0 & 0 & 0\end{array}$	Background EOR Shape
$\begin{array}{c}1 & 1 & 0 & 0 & 1 & 1 & 1 \\0 & 0 & 1 & 1 & 0 & 0 & 0\end{array}$	Background with shape in black EOR Shape (erase)
1111111	Background restored

The result is a black shape surrounded by the white background, producing what might be called a "negative." This actually works quite well if we want the object to appear to be in front of the background as opposed to behind it. The effect is illustrated in the following figure.

To see how this looks in a program, run Program 14-1, which is the same as Program 4-1, except a box has been drawn in the path of the person shape.

As you may have already guessed, the DRAW-DRAW protocol is inappropriate for drawing over backgrounds, because whatever background is in the screen byte will be erased by the shape byte, as there is no restoring function. Try Program 14-2, which is the same as Program 4-3 (DRAW-DRAW) except for a box in the person's path—the box is erased as the person shape passes through it.

The "negative" effect is sometimes inappropriate. For example, when we want a shape to appear to go behind the background or when the background is very simple, such as a single line, the shape should merge with the background as illustrated here.

271

To accomplish this, we need to use a different type of draw routine, one that uses AND and ORA.

We've seen the AND instruction before in the chapter on collisions, but it won't hurt to review it. AND compares each bit in the Accumulator with the corresponding bit of a byte, either a direct value or the contents of a memory location, and returns a value of 1 if both bits are 1. Otherwise, the result is 0. The result is stored in the Accumulator.

Example

Accumulator	0	0	1	1	0	0	1	1
AND byte	0	1	0	1	0	1	0	1
Result	0	0	0	1	0	0	0	1

ORA does the same kind of comparison, but here the result is 1 if either or both bits are 1, and 0 if both bits are 0. The result is stored in the Accumulator.

Example

Accumulator	00110011
ORA byte	01010101
Result	01110111
	and to produce a she

Let's see how we use these instructions to produce a shape merged with a background. First, we obtain a complement of the shape by EORing with #\$7F. We then AND the background with the complement, and ORA the shape:

Shape EOR #\$7F	0011000 11111111	
Result AND background	$\begin{array}{c}1 & 1 & 0 & 0 & 1 & 1 & 1 \\1 & 1 & 1 & 1 & 0 & 0 & 0\end{array}$	
Result ORA shape	$\begin{array}{cccccccccccccccccccccccccccccccccccc$	
Result	1111000	Shape + Background

A problem arises when we now want to erase the shape and restore the background. If we EOR the shape, a flawed background results:

Shape + background	1 1 1 1 0 0 0
EOR shape	0011000
Result	1 1 0 0 0 0 0

We get around this by storing the background in a temporary location labeled BACK, and erase the shape by redrawing the stored background using the protocol LDA byte, STA screen byte. We can see how this works in the next program (Program 14-3), which is the same as Program 14-1 except for the draw and erase routines.

First, we reserve memory for the background by BACK DS 6, because the shape contains 6 bytes. In the DRAW routine, we load the screen byte by LDA (LOW),Y (line 92) and store the byte (i.e., the background) in BACK with STA BACK,X (line 93). We then continue drawing with EOR #\$7F to obtain the shape complement; AND BACK,X to AND the background; ORA SHAPE,X to ORA the shape byte; and STA (LOW),Y to plot the result. X is used as the counter for the BACK "table" the same way it's used as a counter for the SHAPE table. For multiple byte shapes, we would use BACK+1,X, BACK+2,X, etc. in the same way that we use SHAPE+1,X, etc. In the MAIN PROGRAM, after the shape is drawn, we erase by calling an XDRAW routine. Here the background is restored by LDA BACK,X, STA (LOW),Y; i.e., we redraw the background directly over the merged shape + background.

COLOR SHAPES WITH COLOR OR WHITE BACKGROUNDS

Drawing color shapes over color or white backgrounds using the usual EOR DRAW-ERASE routine produces a variety of strange results. For example, if we plot a violet shape over a violet background or a green shape over a green background, the shape turns to black:

	0						Background violet
	0		0	1	0	0	EOR violet shape
1	0	0	0	0	0	1	Shape is black

Plotting blue over blue or orange over orange yields even stranger results. Here the shape not only turns to black but the background turns to the non-high-bit-set color (blue to violet or orange to green), because when the high bit is EORed, it sets to 0 (remember even though the high bit is not plotted, it is still affected by assembly language instructions):

	High	
1 0 1 0 1 0 1 0 0 1 0 1 0 0	1 1	Background blue EOR blue shape
1000001	0	Black shape, violet background

If we plot alternate column colors, say a green shape over a violet background, the shape turns to white:

1010101	Background violet
0001010	EOR green shape
1011111	Shape is white

Similarly, if we plot a blue shape over orange, the shape also turns to white and, in addition, the background turns to the non-high-bit-set color.

If we plot color shapes over a white background using EOR, the color changes to the complement:

 1
 1
 1
 1
 1

 0
 1
 0
 1
 0
 1
 EOR violet shape

 0
 1
 0
 1
 0
 1
 0
 Shape is green

To see the effect of all this, run the following program (Program 14-4), which draws a violet and green shape over a violet background using EOR. What you will see is that the violet part of the shape will turn to black and the green part to white as the shape passes over the background.

In all these cases, the background can be restored by EORing the shape byte, but clearly we need to modify the draw routine to allow the shapes to retain their colors. The technique we're going to use is a slight modification of the protocol presented in Program 14-3. We load the background byte with LDA (LOW),Y and store it in BACK with STA BACK,X. Next, we load the Accumulator, not with the shape byte but rather with a white dummy shape, and use this for the EOR #\$7F and AND BACK,X. We then ORA the color shape and plot. The background is restored from BACK in the XDRAW routine. This technique is used in the following program (Program 14-5) to draw a green shape over a violet background.

--	--	---	---	--	---	---	---

Let's examine the details to see how the program works

Violet background	1 0 1 0 1 0 1 4\$55
Green shape	0 0 0 1 0 1 0 4\$28
White dummy shape	0 0 1 1 1 1 1 4\$7C
White shape	0011111
EOR #\$7F	1111111
Result	1 1 0 0 0 0 0
AND violet background	1 0 1 0 1 0 1
Result	1 0 0 0 0 0 0
ORA green shape	0 0 0 1 0 1 0
Result	1001010
	black

The result is a green shape over a violet background. This is what we want—the colors are retained—but notice that the shape now has a black

border. This is not a great problem. If you run Program 14-5, you'll see that the border actually sets off the shape quite nicely. Eliminating the border is really not necessary for most situations and in fact an equally pleasing effect can be achieved by changing the border to white. All that's required is changing the white dummy shape. For example:

Violet background	1 0 1 0 1 0 1 #\$55
Green shape	0 0 0 1 0 1 0 #\$28
White dummy shape	0 0 0 1 1 1 1 #\$78
White shape	0001111
EOR #\$7F	1111111
Result	1 1 1 0 0 0 0
AND violet background	1 0 1 0 1 0 1
Result	1 0 1 0 0 0 0
ORA green shape	0 0 0 1 0 1 0
Result	1011010
	white

This technique works for drawing any color over a white background and for any color (including white) over any other color background, unless the color combinations involve high-bit-set and high-bit-not-set colors. You can't draw a violet shape over a blue background, for example, because the plotted byte either has the high bit set or not.

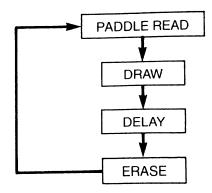

Advanced Paddle (Joystick) Routines

I'm really in a bit of a fix— I need a limerick like a magician needs tricks. But I'm lazy today So I'll take the easy way— Just read the one in Chapter 6.

A he paddle routine in the game program works okay for its stated purpose, but let's see how we can use our assembly language expertise to improve on it and at the same time exercise our programming skills. First, we'll discuss how to minimize flicker by introducing a paddle movement test, and then we'll go on to a paddle-smoothing routine that prevents instantaneous movement of the paddle-controlled shape.

TESTING FOR NON-MOVEMENT OF PADDLE

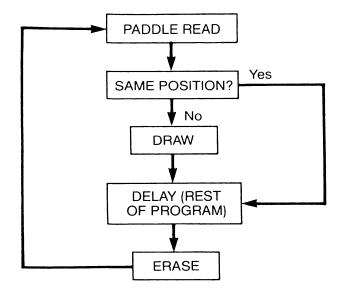

Let's consider Program 6-1, where the vertical movement of a shape is controlled by a paddle. The overall scheme can be represented as follows:

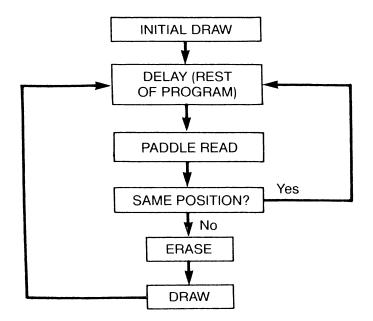

In the game program, "DELAY" can be replaced by "REST OF PROGRAM", because everything else is executed between paddle reads. Now if you look at the man shape in the game program or the shape in Program 6-1, when the shapes are stationary, flicker is evident. As mentioned before, the amount of

flicker depends to a large extent on the image retention characteristics of the monitor or TV. The reason for the flickering is the delay between paddle reads; the longer the delay (or the larger the program code between reads) the greater the flickering. Note also that the flickering is noticeable only when the shape is stationary, i.e., when the paddle position is not changed, and this leads us to the solution to the problem. In the scheme diagrammed above, the shape is drawn and erased continuously, even if the paddle position stays the same. What we need to do then is introduce a test for paddle movement—if the paddle is not moved, the draw-erase cycle will be bypassed, the shape will stay on the screen at the position determined by the paddle, and flicker will be totally eliminated.

If we try to introduce this test using the scheme above, we run into trouble, because the shape is erased before each paddle read and so if the paddle isn't moved, the shape will not be displayed.

We could get around this by using a DRAW-DRAW routine, but this presents its own problems which we'll get to later. To perform the test with a DRAW-ERASE routine, we have to modify our usual draw-erase cycle to an erase-draw cycle preceded by an initial draw outside the main loop; that is:

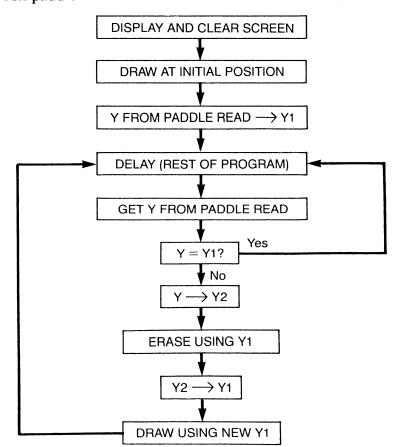

As you can see, the shape is erased and drawn only when the paddle position changes—if it stays the same, the erase-draw routine is bypassed entirely. Note that the shape is drawn, not erased, before the paddle read and test and so always stays on the screen. This scheme is incorporated into the following program (Program 15-1) which is the same as Program 6-1, except for the paddle movement test.

In the MAIN PROGRAM of Program 15-1, we draw the shape initially using a specified screen byte position (defined in the INITIAL subroutine) and a screen line specified by the PDLE subroutine; in this subroutine we also store the Y value returned from PREAD in Y1. The program then proceeds into the main loop, starting with a delay (or rest of program) and then a paddle read. The Y value returned from PREAD is compared to Y1—if equal, it means the paddle position hasn't changed and the program loops back to the delay (rest of program) without erasing and redrawing the shape. Voila, no flicker, or, as they say in French, voila, no flicker.

If Y is not equal to Y1, the paddle position has moved, so we want to erase and then redraw the shape at the new position specified by the paddle read. First, we store the Y value from PREAD temporarily in Y2 and then jump to PLOT to erase the shape using Y1 (the original Y value from the last draw). The value in Y2 is then placed in Y1 and another jump to PLOT draws the shape using the Y value from the last PREAD. In other words, Y1 is used for erasing and Y2 for drawing, then Y2 is placed in Y1 in preparation for the next cycle. After the draw, the program loops to the delay (rest of program), and so on and on and on.

Compare Programs 6-1 and 15-1. The absence of flicker is quite noticeable and quite an improvement, and would be even more so in programs with lots of code between paddle reads.

PADDLE-SMOOTHING ROUTINES

As mentioned above, using a DRAW-DRAW routine would simplify things somewhat, because without an erase routine, the shape will always be on the screen. For example, we could use the following scheme:

However, there is a problem with paddle routines using DRAW-DRAW. Remember that DRAW-DRAW erases by redrawing over a previous position. For vertical movement, a border of #\$00's equal to the maximum shape move must be included in the shape tables. For horizontal movement, a trailing byte #\$00 may be needed, depending on how the shape is drawn. If the jump in position from one paddle read to the next is greater than the border in vertical movement, or larger than one byte in horizontal movement, then shape fragments will be left on the screen. Because the paddle routines we've used so far provide for virtually instantaneous movement, moving the paddle (or more easily the joystick) rapidly does produce large jumps. Try this with Program 6-1. Introduce a border of size 5 or so and convert to a DRAW-DRAW routine; then move the paddle slowly-okay. Then move it rapidly-interesting pattern, no? The solution to this problem (aside from huge, unworkable borders or movement limiters on your paddles) is to limit the maximum shape move regardless of paddle movement. This not only eliminates the DRAW-DRAW problem, but also provides for a smoother, more pleasing effect. In the next program (Program 15-2), we're going to modify Program 6-2 (horizontal movement of the man shape) by limiting the movement to a maximum of 5 bit positions at a time.

Program 15-2 is the same as Program 6-2 except for the PDLE subroutine, so we'll limit our discussion to that part of the program. Examining the flowchart will make this discussion easier to follow. The flowchart for Program 15-2 is on page 294. The two salient memory storage locations are MHORIZ, which contains the Y value used to calculate the shape position, and PDL, which contains the Y value from the most current paddle read.

If MHORIZ is larger than PDL, we want to subtract 5 from MHORIZ but not go below zero. After the subtraction, if MHORIZ is \geq PDL, we continue with the program and use MHORIZ to calculate the new shape position. If MHORIZ < PDL, we don't want to go beyond the paddle position, so we set MHORIZ equal to PDL and then continue with the shape draw. If MHORIZ initially equals PDL, we set MHORIZ equal to PDL and continue. If MHORIZ is initially smaller than PDL, we add 5 to MHORIZ but only if it is below 250 so that we don't go beyond 255. After adding 5, if MHORIZ > PDL we set MHORIZ equal to PDL, again not to go beyond the paddle position. All this occurs just once each cycle, thus limiting the shape movement to a maximum of 5 bit positions in either direction.

..... Advanced Paddle (Joystick) Routines

Run Program 15-2 and compare it to Program 6-2. I think you'll agree the effect is more pleasing and is reminiscent of the type of paddle control one sees in Invader-type games.

The paddle smoothing routine can be used in any program using paddles to move shapes in any direction and the maximum speed of movement can be altered simply by changing the value to be added or subtracted. This routine also allows one to incorporate a DRAW-DRAW routine into the program. For vertical animation, we simply limit the maximum move to the border size. For horizontal animation, we need only limit the maximum move to one byte or less.

One final note. I haven't combined the paddle smoothing routine with the paddle movement test of Program 15-1. This is something for you to do, as we'll talk about in the last chapter.

Integrating **B**ASIC with **A**ssembly Language Programs

There once was a woman named Kit, Whose husband gave her a fit. Computing all night He neglected her plight So they drifted apart, bit by bit.

(This has nothing to do with this chapter, but it's hard writing these things.)

here isn't anything that can be done in BASIC that can't be done in assembly language, but for some things BASIC is much easier. Complex arithmetic, for example, is much simpler using BASIC. In assembly language, you can add, subtract, multiply, and divide, but in BASIC a whole host of arithmetic functions are available, such as SQR, ABS, INT, SIN, COS, TAN, RND, EXP, LOG, etc., and working with formulas is made simpler with the DEF FN instruction (see the Apple BASIC manual for details). Of course, all these functions can be derived from the four basics of adding, subtracting, multiplying, and dividing, but if speed is not required, it's much easier to let the BASIC interpreter do it for you. If speed is required (let's say you want to plot sine curves on the hi-res screen easy but slow in BASIC), you'll need to use assembly language. Deriving sine curve equations from the four basic arithmetic functions is about as much fun as defleaing your dog but fortunately, if you need to do this, there are texts on the market that deal with complex number manipulations using assembly language.

Printing to the text screen is often used with hi-res graphics programs, either for displaying whole page instructions or for printing on the bottom four lines of page 1 with the mixed text and graphics mode. (This is different from printing on the hi-res screen itself—here one needs to use shapes in the form of letters in the same way as we used number shapes for displaying the score in the game program.) Text printing can be done using BASIC or assembly language and in fact is relatively easy with assembly language, because one can use several built-in Apple subroutines to take care of the housekeeping chores. But, to my mind, nothing is easier than the BASIC PRINT statement. The only advantage of assembly language for text printing is speed, but this is like saying you can travel a distance of 1 foot faster going 100 mph than going 50 mph. Printing in BASIC is so fast, unless you're using some kind of convoluted code, that any speed advantage of assembly language is more academic than real.

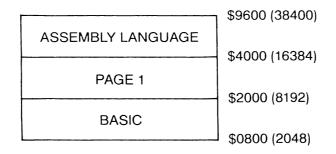

MEMORY ALLOCATION

Dealing with a program that uses both BASIC and assembly language, or with a program that uses both BASIC and hi-res graphics whether or not assembly language is also used, requires that attention be paid to how memory is allocated. We have to be careful that BASIC, assembly language, and the hi-res screens don't run into each other, that is, do not occupy the same memory locations; otherwise, we will be left with an unworkable program. To see how to do this, let's consider first how BASIC uses memory.

On startup, the Apple assigns \$800 (2048) to the bottom of BASIC and \$9600(38400) to the top (for machines with 48K minimum RAM,— see Chapter 2). The reason a top has to be assigned is that while the BASIC program starts at the bottom, variables are stored after the end of the last program line, and string variables are stored at the top and work their way down. Thus, any non-BASIC program code such as assembly language or a hi-res screen between the top and bottom may interfere with the BASIC program itself, especially if string variables are used. Even if they're not, it's always a good idea to reserve an area of memory for BASIC to ensure no overlap with the hi-res screens or with assembly language code. There are two solutions to this problem—we either change the top or change the bottom of BASIC, the particular choice depending on how much memory we want to allocate to the different parts of the program and which hi-res screen we want to use.

There are four basic situations to consider:

1. Page 1 hi-res screen, BASIC below Page 1, assembly language above Page 1:

ASSEMBLY LANGUAGE 22000 BYTES BASIC 6000 BYTES

The bottom of BASIC is the startup address, \$800 (2048). We want to move the top, the area for string variable storage, to the bottom of hi-res screen Page 1, which starts at \$2000 (8192). We do this in the beginning of the BASIC program by

1 HIMEM:8192

(Note that BASIC uses only decimal addresses, not hex.) This instruction ensures that BASIC will occupy a memory block that will not be interfered with by the hi-res screen or the assembly language code. The assembly language program itself could be given a starting address of \$4000, that is, just above Page 1. The result of all this is that BASIC would have about 6000 bytes of available memory,

whereas the assembly language program would have about 22,000 bytes. (If we want to use both hi-res screens, the assembly language program would be started at \$6000 and would have about 14,000 bytes of memory.)

2. Page 2 hi-res screen. BASIC below Page 2, assembly language above Page 2:

· · · · · · · · · · · · · · · · · · ·	\$9600 (38400)
ASSEMBLY LANGUAGE	
······································	\$6000 (24576)
PAGE 2	
	\$4000 (16384)
BASIC	
	\$0800 (2048)

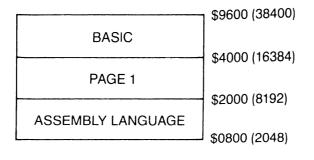

Here we want to move the top of BASIC to \$4000 and we do this by

1 HIMEM:16384

The assembly language code would start at \$6000 and have about 14,000 bytes of memory, and BASIC would have also about 14,000.

3. Page 1 hi-res screen, BASIC above Page 1, assembly language below Page 1:

ASSEMBLY LANGUAGE 6000 BYTES BASIC 22000 BYTES

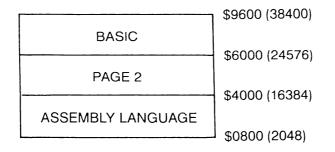

Moving the bottom of BASIC is a little more complicated than moving the top. There is no single command to do this; rather a series of POKEs is required. Locations 103 and 104 have to be POKEed with certain values and the new start of BASIC has to be POKEed with zero because BASIC must always start with zero in the first position. There is a formula that can be used to calulate the values to be POKEed into 103 and 104, but the easiest thing to do is incorporate the formula into a BASIC instruction itself and let the program do the calculating for you. What we do is set up a separate program called a "loader" program and use

it both to change the bottom of BASIC and run the main program. The "loader" program consists of one line (make sure you save the program before running it because it self-destructs on running):

1 LOC = 16384 + 1:POKELOC - 1,0:POKE 103,LOC - INT(LOC/256) * 256: POKE 104,INT (LOC/256): PRINT CHR\$(4); "RUN PROGRAM"

Running this program will set the bottom of BASIC to \$4000 and will run the main program labeled PROGRAM, assuming of course it's on the same disk. In this case, BASIC will have about 22,000 bytes of available memory and the assembly language program about 6,000 bytes, assuming we start it at \$800.

4. Page 2 hi-res screen, BASIC above page 2, assembly language below Page 2:

ASSEMBLY LANGUAGE 14000 BYTES BASIC 14000 BYTES

The only change here is defining LOC in the "loader" program as 24576 + 1. Now both BASIC and the assembly language program will have about 14,000 bytes of available memory.

These are the four basic memory allocation situations, but variations are sometimes required. For example, and as mentioned above, if we want to use both hi-res screens, things would have to be shifted around, removing memory from either BASIC or the assembly language program, depending on the particular configuration we want. Also, because we can start the assembly language program anywhere, the actual memory available for assembly language is variable.

Other situations may require other changes. For example, suppose we're using the number 3 configuration with BASIC above Page 1. If our assembly language program requires 8,000 bytes instead of the 6,000 available, we could move the bottom of BASIC to around 19,000 instead of 16,384 and use the extra memory for assembly language code. We could use this memory block, for example, to store our line address and offset tables. Assembly language programs do not require a continuous block of uninterrupted memory, but when we split up such a program, we have to be careful where we do it. For example, we wouldn't want an interruption in the middle of a draw routine. We can, however, place any block of code that is accessed only by its label anywhere we want. The only caveat, as discussed before, is that relative branch instructions have a range limited to 127 bytes forward and 128 bytes back—in these cases, we use the relative branch to go to a nearby JMP instruction, which has no range limitation. In the example cited above, we would set up our main program with ORG \$800

and place the line address and offset tables starting at \$4000, making sure they do not extend into the start of BASIC.

The particular configuration we would choose obviously depends on the program requirements. If we need Page 1 to display mixed text and graphics, we must use configuration 1 or 3. If the assembly language program is long and BASIC short, we would choose 1; conversely, configuration 3 would be appropriate for long BASIC and short assembly language programs. Keep in mind that because we can place assembly language blocks almost anywhere we want and we can vary the top and bottom of BASIC, there is a large amount of flexibility in how to allocate available memory for any particular program application.

If your program lengths are running close to the available memory limits, it's important to know the program size so you can plan accordingly. This is no problem with assembly language programs, as most assemblers will display the length in bytes after assembly. To determine the length of a BASIC program in bytes, load the program and type in the following instructions (with thanks to Beagle Bros.):

PRINT (PEEK (175)) + PEEK (176) * 256) - (PEEK (103) + PEEK (104) * 256)

If you find your programs are too large to fit, don't despair just yet. Assembly language programs can be shortened by writing more efficient code, but this is probably applicable only to very experienced programmers. An easy trick to extend total available memory is to include the following as the first line of your BASIC program:

1 PRINT CHR\$(4);"MAXFILES1"

This extends the upper limit of memory from \$9600 (38400) to \$9AA6 (39590) (for 48K minimum machines), making available an extra 1,190 bytes. The price you pay for this is that only one text file can be open at one time (see the Apple DOS Programmer's Manual for more details). Another thing you can do is use one of the commercially available optimizing programs, such as those available from Beagle Bros., to crunch your BASIC programs. You'd be amazed at how much space can be saved using one of these utilities, but save this for last—such crunched programs are virtually impossible to edit. If you're really desperate, try one of the DOS mover programs (if you have 64K)—you can realize some 10,000 bytes of extra memory this way.

ZERO PAGE USAGE

We mentioned in a previous chapter that we have to be careful in choosing which zero page addresses to use in our assembly language programs. This is because zero page is used extensively by Applesoft BASIC and DOS and so if we're using BASIC along with our assembly language program or if we're using DOS commands, either from BASIC or from assembly language, we have to search for "open" zero page addresses and there aren't many. For the Apple IIe, safe zero page addresses are \$06 to \$09, \$1A to \$1C, \$EB to \$EF, and \$F9 to \$FC. These are probably okay for other Apple IIs but I would check the Reference Manual for your particular machine just to make sure. Of course if you're not using BASIC or DOS, then any zero page address can be used, but it's probably best to stick with the safe ones—you never know when you might be adding DOS commands or BASIC to your assembly language program.

GRAPHICS AND TEXT COMMANDS FROM BASIC

You've seen some of these instructions before in Chapter 3 and they are all described in the Apple BASIC manual but some rather obtusely—a brief review is worthwhile.

GR Clears and displays low resolution screen.

HGR Clears and displays hi-res screen Page 1 (mixed text and graphics with the bottom four lines displaying text).

HGR2 Clears and displays hi-res screen Page 2.

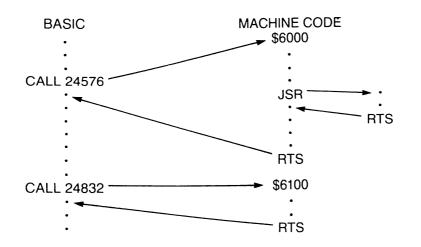

TEXT Displays the full screen text page without clearing it.

- **HOME** Clears but does not display the text page and sends the cursor to the top left position. When used with hi-res screen Page 1 in mixed text and graphics mode, the bottom four lines are cleared and the cursor is positioned at VTAB 21 without affecting the graphics display. The combined instructions TEXT:HOME will display and clear the entire text page regardless of which hi-res screen is being used.
- **POKE 49232,0 (or POKE 16304,0)** (In this and the following examples, either number can be POKEed but Integer BASIC requires poking the negative number.) Accesses the graphics mode, either lo-res or hi-res depending on the status of other soft switches, without clearing the graphics screen.
- **POKE 49233,0 (POKE 16303,0)** Selects the text page without clearing it: the text page margins can be altered to produce a text "window;" unlike the TEXT command, this instruction leaves the text "window" settings intact.
- POKE 49234,0 (POKE -16302,0) Selects full screen graphics for hi-res screen Page 1.
- **POKE 49235,0 (POKE 16301,0)** Selects mixed text and graphics for hi-res screen Page 1 (not necessary after an HGR if full screen graphics has not been selected).
- POKE 49236,0 (POKE -16300,0) Selects Page 2 without clearing it.
- POKE 49237,0 (POKE -16299,0) Selects Page 1 without clearing it.
- **POKE 49238,0 (POKE 16298,0)** Selects low resolution mode (not necessary after a GR).
- **POKE 49239,0 (POKE 16297,0)** Selects high resolution mode (not necessary after an HGR or HGR2).

ACCESSING ASSEMBLY LANGUAGE PROGRAMS FROM BASIC

When combining BASIC with assembly language, program control essentially rests with the BASIC program. A particular assembly language program address is

accessed from BASIC by the instruction CALL *address* (decimal). Thus, the command CALL 24576 would send the program to the machine code beginning at \$6000. The program returns to BASIC when it reaches an RTS opcode that does not follow a JSR. If there is no such RTS, the program remains in the assembly language portion. For example:

To see how this works in an actual program, let's use BASIC in our game program to display the game instructions before starting. On our disk we would have the game program labeled GAME. The BASIC program would look like this:

```
10 PRINT CHR$(4);"BLOAD GAME,A$6000"
20 TEXT:HOME
30 PRINT "GAME INSTRUCTIONS ..... PRESS ANY KEY TO CONTINUE"
40 GET A$
50 HGR:POKE -16302,0
60 CALL 24576
```

One of the advantages of using BASIC is that BASIC commands often can substitute for assembly language code. In this instance, for example, HGR is used to display and clear the Page 1 hi-res screen and POKE -16302,0 displays full screen graphics. As this is done in the beginning, speed is not required, and the call to Page 1 full screen graphics and the clear screen routines in the GAME program become unnecessary and can be deleted. Once the call to \$6000 is made, the program stays entirely in the GAME program, because there is no RTS not preceded by a JSR.

Let's modify the GAME even further by changing the restart protocol. In the STOP2 subroutine, instead of the *press any key* routine we substitute an RTS. When the game ends, this will send the program back to BASIC where we will now display another text screen containing, for example, a scoring summary:

70 TEXT:HOME 80 PRINT "GAME SUMMARY.... PRESS ANY KEY TO CONTINUE" 90 GET A\$ 100 GOTO 50

The TEXT instruction calls the text screen and HOME clears it. We restart the game by going back to line 50. Alternatively, if we want to display the game instructions again, line 100 would read GOTO 20. Other variations are possible.

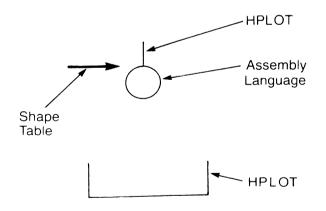

Suppose we want to restart just by going back to the game instructions:

70 GOTO 20

This combination of printing in BASIC and displaying graphics in assembly language is quite easy and very useful, not only for game programs but also for a multitude of other applications. In addition, BASIC can be used not only for printing but also for graphics itself, in conjunction with assembly language graphics. This is possible because the hi-res screen doesn't care where its instructions come from and so one can freely intermix graphics from BASIC, assembly language, and even from Apple shape tables. The only caveat is that pleasant results are obtained only if the non-assembly language graphics do not involve themselves in routines that require speed and smooth animation. Perhaps the greatest utility of this type of intermixing is in educational programs. Such programs generally do not involve continuous, rapid animation as in games, but rather present a series of lessons, each one consisting of some text and a graphics presentation that consists only partly of animation routines.

To see how we can profitably mix text and graphics from a variety of sources, let's design a small educational program that illustrates the principle that objects fall down unless restrained (the profit comes from selling the program to kindergarten computer workshops). We're going to use hi-res screen Page 1 with mixed text and graphics and use the bottom four lines for the explanatory text. Because our BASIC program is small, we'll place it below Page 1 with HIMEM:8192. We're also going to use a shape table and we'll load this above Page 1 at \$4000 (16384). The assembly language program will be loaded above the shape table, at \$6000 (24576).

The screen will show a ball suspended by a rope above a container.

After some text instructions, the rope will be cut at a site indicated by an arrow—the arrow will then disappear and the ball will fall into the container. The container and rope will be drawn from BASIC by HPLOTting. The arrow will come from the shape table (designed with the aid of a utility program such as Apple Mechanic from Beagle Bros.) and the ball will be drawn and animated with our assembly language program. The Page 1 screen will be displayed and cleared from BASIC and we can begin the assembly language program at \$6000 with just drawing the ball. This draw routine ends with an RTS, say at \$64FF, and thus will return to BASIC once the ball is drawn. At \$6500 (25856), the program continues with the ball animation and also ends with an RTS to get back to

BASIC again. The program would look like this (the shape table and assembly language program will already have been BSAVEd on the disk:

1 HIMEM:8192 :REM BASIC BELOW PAGE 1

The variations on this theme are endless. We could clear the screen with HGR and continue with more graphics from any source; we could draw the container, rope, and arrow in color by specifying a color with HCOLOR and, of course, draw the ball in color in the assembly language program; we could make a larger container by changing SCALE; we could switch back and forth from text to graphic screens without erasing them by using the appropriate POKEs, and so on. The reason this works is that HPLOT and DRAW are very fast for simple shapes that are displayed and not moved—assembly language is required only for the animation. And let me emphasize that assembly language is indeed required—moving the ball around from BASIC or shape tables would produce an animation that would immediately mark you as a rank amateur, deserving only of scorn. From personal experience, I can tell you that professional-looking animation is a strong selling point for these types of programs.

e've covered quite a bit since constructing the game program, but, of course, the coverage has not been exhaustive (and I don't mean it hasn't been tiring). My hope is that this book has provided the necessary background in hi-res assembly language graphics so that you can now profitably examine more advanced texts and those rather obtuse (I hope now less obtuse) magazine articles that pop up now and then to learn even more about this subject, either for constructing your own games or indeed for any of the many other applications that find hi-res graphics useful. You may not know enough yet to construct a really super arcade-type game, but you certainly have the knowledge to produce professional results for interesting games and for educational and other types of programs. And, of course, you've also learned something about how to use assembly language other than just to move numbers around.

As mentioned in the Introduction, any learning process is enhanced by doing and not just observing. In this spirit, below I will discuss suggestions for modifying the game program using techniques covered in Parts One and Two that were not incorporated into the game. You may find that going through the exercises in this chapter will teach you more about hi-res graphics and assembly language than all the other chapters combined, and so I urge you to sharpen your typing fingers and go to work.

1. Use the DRAW-DRAW protocol for both the man and the plane, making sure to incorporate the appropriate borders. As neither shape is used for collision detection, DRAW-DRAW will work and will produce smoother animation. For the man shape, use the paddle smoothing routine (necessary for DRAW-DRAW as discussed in Chapter 15) and the test for non-movement of paddle to eliminate flicker. **2.** Work on the sound routines for the plane and explosions and perhaps for the bullet firing.

3. Have planes appear at several different line positions and have some going right to left instead of just left to right. Make sure each line position is some multiple of 8 from the bullet firing line to ensure collision detection with the bullet; alternatively, use multiple line collision testing with the bullet shape.

4. Have the planes drop bombs and use the bomb shape for collision testing. Use the line position of a collision to determine what the bomb has hit—if at the bottom, it hits the bottom line; above the bottom, but not above the top of the man, it hits the man; above the man, it hits a bullet. Include an explosion routine for each collision. Have the game end if the man is hit.

5. Change the scoring protocol to decrement by 1 each time a bullet is fired, increment by 3 for each plane hit and by 5 for each bomb hit. A plane is hit if only a bullet detects a collision. A bomb is hit if both the bomb and bullet detect a collision.

6. Use BASIC to display the game instructions.

7. Draw the plane in color, changing the bullet shape to a width of 2 bits to ensure collision detection. Draw the explosion shapes in orange and yellow. Draw flickering orange lines directly behind the plane to simulate engine exhaust. Enlarge the man shape and draw in color.

8. Reprogram the game in double hi-res and in double hi-res color. For the latter, use dummy white shape tables for collision detection.

Well, that's it. Good luck—and remember, #\$2B or not #\$2B is not the only question.

Appendix: Assembly Language Commands

306

⊥ V ot all assembly language commands for the Apple II 6502 microprocessor are listed here, mainly just those referenced in the text. In addition, the descriptions are not comprehensive. A complete set, with complete descriptions, can be found in texts on assembly language programming. I especially recommend *Assembly Lines: The Book,* by Roger Wagner, Roger Wagner Publishing Co., Santee, CA, 1982.

ADC (ADd with Carry) Adds the contents of a memory location or a direct value to the contents of the Accumulator, plus the Carry bit if it was set. The result is stored in the Accumulator. ADC is usually preceded by a CLC in case the Carry bit has inadvertently been set. A common use of ADC is to add two numbers together.

Example

CLC LDA #\$01 ADC #\$01 ;Accumulator now contains #\$02

CLC LDA #\$01 ADC \$4000 ;\$4000 contains #\$04 STA \$5000 ;\$5000 now contains #\$05

AND (Logical AND) Compares each bit of the Accumulator with each corresponding bit of the contents of a memory location or a direct value. If both bits are 1, the result is 1; otherwise the result is 0. The result is stored in the Accumulator. This command is useful for collision detections.

Example

Accumulator	0	0	0	1	1	1	0	1
Number	0	1	1	1	0	1	0	0
Result	0	0	0	1	0	1	0	0

ASL (Arithmetic Shift Left) Each bit of the Accumulator or the contents of a memory location is moved one position to the left. A 0 is placed in bit 0 (the rightmost bit) and the high bit is placed in the Carry. One use of ASL is to multiply by factors of two.

C <--- 7 6 5 4 3 2 1 0 <--- "0"

BCC (Branch on Carry Clear) The branch is taken if the Carry bit is clear; i.e., zero. The pseudo-op BLT (Branch if Less Than) can be used by some assemblers, because BCC is often used after a comparison instruction to test if the Accumulator holds a value less than a specified value; if it does, the Carry bit is clear and the branch is executed.

Example

LDA #\$05 CMP #\$06 BCC CONTINUE ;The branch is taken

BCS (Branch on Carry Set) The branch is taken if the Carry bit is set, i.e., 1.

The pseudo-op BGE (Branch if Greater or Equal) This can be used by some assemblers as BCS is often used after a comparison instruction to test if the Accumulator holds a value equal to or greater than a specified value; if it does, the Carry bit is set and the branch is executed.

Example

LDA #\$05 CMP #\$04 BCS CONTINUE ; The branch is taken

BEQ (Branch if EQual) Branches if the result of a previous operation is zero. It is often used to compare the value in the Accumulator or the contents of a memory location to a specified value, which itself can be the contents of a memory location or a direct value. If the values are equal, the branch is taken.

Example

LDA LINE CMP DEPTH BEQ CONTINUE ;The branch is taken if LINE = DEPTH

BEQ can also be used to test for a register reaching a zero value.

Example

	LDY #\$06	
LOOP	LDA \$4000	
	STA \$5000	
	DEY	
	BEQ CONTINUE	;The branch is taken when $Y = 0$
	JMP LOOP	

BIT Compare Accumulator BITs with contents of memory. BIT can be used to access a soft switch without changing the contents of the Accumulator.

Example

BIT \$C030 ;Tweaks speaker

BMI (Branch on MInus) Branches if any operation produces a result in the range #\$80 to #\$FF, i.e., high bit set. One use is to test for a keypress.

Example

LOOP	

LDA \$C000 ;If no key pressed, value < #\$80
 BMI CONTINUE ;Branches if key pressed
 JMP LOOP

BMI can also be used to terminate a loop when a value reaches any number from #\$80 to #\$FF.

Example

```
LDY #$70
LOOP DEY
BMI CONTINUE ;Branch taken when Y wraps around to #$FF
JMP LOOP
```

BNE (Branch on Not Equal) Branches if the result of any operation is non-zero.

Example

LDA #\$06 CMP #\$05 BNE CONTINUE ;Branch is taken

BNE can also be used in loops to test for non-zero.

Example

	LDY #\$06	
LOOP	DEY	
	BNE LOOP	;Branches until Y = 0
	RTS	
	RTS	

BPL (Branch on PLus) Branches if any operation produces a result in the range #\$00 to #\$7F, i.e., high bit not set. BPL can be used to test for a key press.

Example

LOOP	LDA \$C000	;If no key pressed, value $<$ #\$80
	BPL LOOP	;Branches until key is pressed
	JMP CONTINUE	

BPL can also be used to terminate a loop when a value reaches any number outside the range #\$00 to #\$7F.

Example

LOOP	LDY #\$70 DEY	
	BPL LOOP RTS	;Branches until Y = #\$FF

Note: Conditional branches are limited to 127 bytes forward and 128 bytes back.

- **BRK** (BReaK) Halts execution of the program. This command is useful for debugging programs. By placing BRK at strategic locations, the program can be stopped and the status of the registers and memory locations examined.
- **CLC** (CLear Carry) Clears the Carry bit; usually used preceding an ADC instruction in case the Carry bit has been set accidentally somewhere else in the program. It can also be used to force a branch.

Example

CLC

BCC CONTINUE ;Branch always taken

CMP (CoMPare to Accumulator) Compares the value in the Accumulator to a direct value or to the contents of a memory location. CMP is used with comparison instructions for conditional branches.

Example

LDA #\$06 CMP #\$07 BCC CONTINUE

CPX (ComPare to X register) Compares the contents of the X register to a direct value or to the contents of a memory location; used with conditional branch instructions.

Example LDX #\$00 LOOP LDA LINE,X STA LINEA INX CPX #\$05 BCC LOOP ;Branches until X = 5 RTS

CPY (ComPare to Y register) Compares the contents of the Y register to a direct value or the contents of a memory location; see CPX.

DEC (DECrement) Decrements the contents of a memory location by one. If the location contains #\$00, the value will wrap around to #\$FF.

Example

LDA #\$00 STA \$4000 DEC \$4000 ;\$4000 now contains #\$FF

DEX (DEcrement to X register) Decrements the X register by one; see DEC.

DEY (DEcrement the Y register) Decrements the Y register by one; see DEC.

EOR (Exclusive-OR with Accumulator) Each bit of the Accumulator is compared to the corresponding bit of a direct value or the contents of a memory location. If either bit is 1, the result is 1; if both bits are 1 or 0, the result is 0. The result is stored in the Accumulator. EOR is useful in drawing routines for both drawing and erasing.

Example

Accumulator	1	0	0	1	1	0	0	0
Number	0	1	0	1	0	1	1	0
Result	1	1	0	0	1	1	1	0

- **INC** (INCrement memory) Increments the contents of a memory location by one. If the location contains #\$FF, the value will wrap around to #\$00 (see DEC).
- **INX** (INcrement the X register) Increments the X register by one; see INC.

INY (INcrement the Y register) Increments the Y register by one; see INC.

JMP (JuMP to address) Sends the program to the specified address.

JSR (Jump to SubRoutine) Analogous to a GOSUB in BASIC, JSR sends the program to a subroutine at a specified address. When an RTS in the subroutine is encountered, the program returns to the program line immediately following the JSR (see RTS).

LDA (LoaD the Accumulator) Loads the Accumulator with a direct value or the contents of a memory location.

Example

LDA #\$05;Accumulator contains #\$05LDA \$4000;Accumulator contains contents of \$4000

- LDX (LoaD the X register) Loads the X register with a direct value or the contents of a memory location; see LDA.
- **LDY** (LoaD the Y register) Loads the Y register with a direct value or the contents of a memory location; see LDX.
- **LSR** (Logical Shift Right) Opposite of ASL; each bit of the Accumulator or the contents of a memory location is moved 1 position to the right. A zero is placed in the high bit and bit 0 (the rightmost bit) is placed in the Carry bit. One use of LSR is to divide by factors of 2.

"0" ---> 7 6 5 4 3 2 1 0 ---> C

- **NOP** (No OPeration) This does what it says; no operation is performed, but time is used. NOP is used for debugging by disabling certain steps and can also be used as a time delay.
- **ORA** (Inclusive OR with Accumulator) Compares each bit of the Accumulator with the corresponding bit of a direct value or the contents of a memory location. If either or both bits are 1, the result is 1; if both bits are 0, the result is 0. The result is stored in the Accumulator.

Example

Accumulator Number	-				0 0				_
Result	0	1	1	1	0	1	1	1	

ROL (ROtate Left) Each bit of the Accumulator or the contents of a memory location is moved one position to the left. The Carry bit is placed into bit 0 and is replaced by the high bit (see ASL).

C <--- 7 6 5 4 3 2 1 0 <--- C

ROR (ROtate Right) Each bit of the Accumulator or the contents of a memory location is moved one position to the right. The Carry bit is placed in the high bit and replaced by bit 0 (see ROL).

C ---> 7 6 5 4 3 2 1 0 ---> C

- **RTS** (ReTurn from Subroutine) Returns the program to the line immediately following the JSR call to the subroutine (see JSR). An RTS without a preceding JSR is used to return the program to BASIC when the assembly language program is called from BASIC.
- **SBC** (SuBtract with Carry) Subtracts the contents of a memory location or a direct value from the Accumulator and also subtracts the opposite of the

Carry. The result is stored in the Accumulator. SBC should always be preceded by SEC prior to the first subtraction.

Example

LDA #\$05 SEC SBC #\$03 ;Accumulator now contains #\$02

SEC (SEt Carry) Sets the Carry bit to 1. Used before a SBC instruction and also can be used to force a branch.

Example

SEC BCS CONTINUE ;Branch always taken

STA (STore Accumulator) Sends the contents of the Accumulator to a specified memory location. The Accumulator is not affected.

Example

STA \$4000 ;\$4000 contains contents of Accumulator

STX (STore the X register) Sends the contents of the X register to a specified memory location (see STA). The X register is not affected.

STY (STore the Y register) Sends the contents of the Y register to a specified memory location (see STX). The Y register is not affected.

- **TAX** (Transfer Accumulator to X register) Transfers the contents of the Accumulator to the X register. The Accumulator is not affected.
- **TAY** (Transfer Accumulator to Y register) Transfer the contents of the Accumulator to the Y register. The Accumulator is not affected (see TAX).
- **TXA** (Transfer X to Accumulator) Sends the contents of the X register to the Accumulator. The X register is not affected. Combined with TAY, can be used to transfer a value from X to Y.

Example

LDX #\$05	;#\$05 in X
ТХА	;#\$05 in A
ΤΑΥ	;#\$05 in Y

TYA (Transfer Y to Accumulator) Transfers the contents of the Y register to the Accumulator. The Y register is not affected. Combined with TAX, can be used to transfer a value from Y to X.

Example

LDY #\$05	;#\$05 in Y
ΤΥΑ	;#\$05 in A
ТАХ	;#\$05 in X

ABOUT THE AUTHOR

Leonard I. Malkin teaches and does research in biochemistry at a leading midwest medical school. He is a member of the medical school committee on CAI (Computer Assisted Instruction) and has published several commercially successful educational programs for the Apple II. He is also president of his own educational software corporation and is currently engaged in developing other educational programs for the Apple. His immediate plans are to "use the proceeds from this book to buy myself a boat and get away from computers for a while they're driving me crazy."

Hi-Res Graphics and Animation Using Assembly Language

Leonard I. Malkin, Ph.D.

Explore the secrets of double hi-res and color and learn how to create startlingly detailed animated graphics.

This is *the* book for both beginners in assembly language programming and assembly language literates who wish to extend their expertise to Apple II hi-res graphics and animation.

Whereas most books on assembly language do not feature hi-res graphics, this book uses hi-res graphics and animation as a tool to demonstrate the fundamentals of assembly language programming. At the same time, this easy-to-read and sometimes humorous book will show you the secrets of producing professional hi-res animated graphics for games and a variety of other applications.

In the first part of the book, following a discussion of binary and hexadecimal numbering systems and the use of an assembler, you will be guided through each step leading to the construction of a single arcade-type game written entirely in assembly language. Various aspects of hi-res animated graphics are covered with clear, concise explanations. Illustrated with detailed programs, topics include: vertical and horizontal movement, internal animation, paddle and joystick controls, collisions and explosions, scoring, sound generation, and the animation of multiple shapes.

The second part of the book explores color graphics and double hi-res techniques and requirements, including double hi-res color. Other topics in Part Two include curved and diagonal movement, drawing over backgrounds, more sophisticated paddle and joystick controls, integrating BASIC with assembly language, and the use of BASIC and assembly language graphics for educational programs.

Pascal Programs for Data Base Management

Tom Swan

The best bargain in data base management to date! This package contains a complete relational data base system (thirty-one programs and four library units)—ready to run—in Apple Pascal.

The software contains the source codes for all the programs. In the accompanying book, the author explains how to create, edit, merge, search, and sort data files. Two powerful commands that distinguish a relational data base are presented in the programs *join* and *project*. With the help of these two programs, it is possible to extract and prepare any conceivable combination of information from a data base. Also included is *pdbsunit*, a special library of powerful Pascal procedures for input, output, and special data base functions. 7272-4, Book/Software, 3 disks
